Dr. W. A. PUSEY of Chicago said that, of course, we could only surmise to a certain extent as to the process which caused the patient's death, but it seemed to him that we could reasonably conclude that it was one in which the patient was in a condition of excessive hypersensitiveness to tuberculous toxins. She showed an excessive reaction, giving evidences of acute poisoning within twenty-four hours after the injection. That would exclude the reaction from contaminating infection, and so far as he could judge, the case was one of those inevitable misfortunes that sometimes happen from a condition of excessive anaphylaxis to various poisonous substances.

Dr. D. W. MONTGOMERY of San Francisco said it occurred to him that this patient might have been tuberculous, and that this process was causing the lupus erythematosus. Therefore, the tuberculin might have excited this toxin into greater activity, and thus caused death. That would be one explanation.

Dr. S. POLLITZER of New York City thought it would be a misfortune if, on the basis of this experience and a few others reported, we were to give up so valuable a remedy as tuberculin injections. The present tendency in the use of tuberculin was to give much smaller doses than 1/100 milligram as an initial dose, and if 1/1000 or 1/10,000 were given, we possibly would avoid accidents. So far nothing had happened from the use of 1/10,000 of a milligram of tuberculin. If the patient bore that well, further injections could be given.

Dr. PUSEY thought, before passing over this discussion, the point ought to be made that in a given patient, in a condition of anaphylaxis, an incredibly small amount of an anaphylactic substnce produced reaction, and that we were open to these anaphylactic actions in spite of the most excessive precaution and the greatest skill.

Xeroderma Pigmentosum Attributed to Excessive Sun Exposure.—Dr. THOMAS CORLETT of Cleveland, Ooio, had had two cases of this disease. One, a boy of five months old, had whooping cough, and the nurse was instructed to keep him out of doors. The baby became thoroughly tanned. But one day the nurse allowed the strong sunshine to strike the left side of the face of the child while it was asleep, producing a severe sunburn. About three months later freckles appeared on this area and gradually extended over the entire face to a less extent, to the neck, forearms, and back of the hands. The skin became rough and slightly scaly, and three or four excrescences appeared, one on the left eyelid, preventing the child from opening the eyelid, and one on the left temple, the size of a small pigeon's egg, and one on the forehead, to the left of the median line. The eyelid tumor degenerated in the course of about a year into a well-defined malignant epithelial growth. This was confirmed by histological examination. The child was now three years of age; the disease had gradually progressed, and it was not believed the child would survive many months. The second patient was a male, aged 70, resident in Mexico. He had enjoyed good health except that his skin was easily inflamed on exposure to the sun and was covered with freckles. The disease affected the tips of the elbows and knees, other parts of the extremities, the face, and to a slight degree the trunk. The appearance of the lesion suggested parapsoriasis. He had undergone treatment from time to time, but had obtained the best results from some hot sulphur springs. There was now on the index finger of the left hand an ulcerating lesion, which the author thought to be an epithelioma. There was also one near the base of the nose. The patient had a light skin, which did not tan, but freckled when exposed to the sun. The first case was classic of xeroderma pigmentosum, followed by fungoid tumors, which developed into epitheliomata. In the second case the skin showed nutritive disturbances resulting in a condition like that seen in the first case.

Officers Elected.—The following officers were elected for the ensuing year: *President*, Dr. S. Pollitzer, New York City; *Vice-President*, Dr. Martin F. Engman, St. Louis; *Secretary-Treasurer*, Dr. Oliver S. Ormsby, Chicago.

New York City was selected as the next place of meeting.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held May 7, 1914.

THE PRESIDENT, DR. WILLIAM M. POLK, IN THE CHAIR.

THIS meeting was held under the auspices of the Section on Orthopedic Surgery.

Intraarticular Silk Reinforcement of Flail Joints in Poliomyelitis Paralysis.—Dr. BERNARD BARTOW of Buffalo, N. Y., read this paper. He stated that the procedure which he wished to describe was based on other operative procedures in which paraffined silk tendons were used in the treatment of paralysis of poliomyelitis. Briefly outlined, the technique in applying the procedure to any of the large joints was as follows: (1) The silk strands were inserted in the bones in localities where their tension would furnish mechanical resistance for control of motion and posture. (2) Tunnels were drilled through parts of the bones entering into the formation of the joint, the drill in its progress passing through the joint; tunnels were made under the soft tissues close to the bones, the drill in this instance also penetrating capsular tissues in its path. The general design in their construction being one tunnel through the bones and joint, and another parallel and close to the bones under the soft tissues, passing through the joint whenever practicable. (3) Short incisions, three-fourths of an inch long, were made at points over the bones, where the drills entered and emerged, each pair of tunnels having incisions in common. (4) Before withdrawing the drill a loop of bronze wire was threaded into its eye and pulled through each tunnel, the free ends and loop protruding from the incisions. (5) A prepared silk thread was placed doubled in the wire loop and pulled through the bone tunnel, the other being drawn through the tunnel in the soft tissues in the same manner. The ends of each strand were defined, then the leg or arm to be "limited" was held in the desired position, and the strands tied separately to avoid large knots. After this had been done, *e.g.*, in the knee, the leg remained in nearly full extension if there had been a drop knee; and in slight flexion if there had been a genu recurvatum; in the shoulder, the head of the humerus was held close to the glenoid cavity, obliterating the depression beneath the acromion; in the foot the posture was one of the over-corrections of efficiency or weight bearing. Incisions were sutured and dressed, and the joint immobilized by a plaster cast. This procedure had been employed

in all forms of paralytic talipes. It had been used alone and in combination with tendon transposition and remodeling of bones. In paralytic talipes combination was more effective than either procedure when used alone, except in mild forms of paralysis and also when this operative plan was employed comparatively early after the initial disease; in the latter event silk reinforcement alone was sufficient for maintaining posture when tendon transposition would have been admissible. For flail conditions in the knee, of both long and short duration, and all degrees of severity, it had been adapted to incompetencies in both the anterior and the posterior groups of muscles. Dependence could be placed on silk reinforcement in the knee to control postures helpful to recovering function, and afforded higher muscles an opportunity to act. The same might be said concerning the intraarticular suspension of the humerus from the acromion, in the deltoid form of paralysis. As yet the flail hip joint had not been reinforced in this manner, mainly because the depth of the joint was regarded as too great an obstacle. This plan promised the following advantages which other procedures did not: The reinforcement took place within the joint, partly by mechanical fastening due to the silk insertion, and partly by organized exudates resulting from surgical reaction, *plus* the presence of silk. Experience with procedures intended to nullify motion in joints removed apprehension that ankylosis would follow by this plan. There were good reasons for the belief that only limiting processes would occur that would supply resistance for sustaining body weight; that these could be controlled in extent and effect by post-operative protection of the joint, and, finally, that recovery in impaired muscle groups in so far as that was probable, would not be obstructed. Hitherto there had been no operative treatment that had been adapted to the period between the sixth and twenty-fourth month after the initial disease. The author had departed from the established custom by employing this method as early as the sixth month after the onset in a few cases, and between that time and the twelfth month in a large number of instances, with marked advantage in the rate and character of the improvement as compared with results obtained by routine non-operative methods. The simplicity of the operative technique also rendered it practical in very young patients, debarred from operation on account of age and possible interference with reestablishment of function. Neither mutilation of the joint or alteration in its articular surfaces occurred by this plan. The drills used were of special construction, a number being necessary, because of the different curves given to the lines of direction in the tunnels. Post-operative reaction was not severe or productive of much pain if care was taken to immobilize the joint. This should include the pelvis when the knee was the site of the operation. After nine months of controlled posture the whole weight might be allowed to fall on the unprotected foot. Secondary reinforcement had not been frequently required by this plan, but because of its simplicity one might be tempted to err on the side of diminished protection. Usually light brace support might be employed after three months weight bearing with this assistance being unattended by much discomfort. There had been no instances of infection attending implantation of silk in any of their operations. In two instances small serous cysts had formed on the malleoli due to pressure from the knots. The procedure had been without mortality in their hands. His paper was illustrated by means of lantern slides.

Obstetrical Paralyses.—Dr. T. Turner Thomas of Philadelphia, Pa., read this paper. He called attention to his publications on this subject and said that he had little new to offer since the last paper which appeared in the February number of the Annals of Surgery. However, he was glad of this opportunity to bring the subject up again, as he was concerned, lest the very radical views which he had expressed might not receive the serious consideration of the more conservative members of the profession. Every one of the shoulder conditions which he had discussed involved a problem which still remained unsolved. It had been his purpose to show that these conditions were closely related to each other etiologically, and that the varying clinical signs could be traced to an essentially common anatomical basis. Füstner, in 1889, suggested that the mild cases of obstetrical palsy in which the paralysis disappeared in a few days, might have been due to blood extravasions, the pressure of which paralyzed the nerves. Further symptoms, he said, depended on nerve pressure by a diaphyseal fragment in an epiphyseal separation. He believed that in most cases they were not dealing with paralyses, but with undiagnosed epiphyseal separations. In addition to this the author cited von Bramann to show that injuries to the brachial plexus had not been universally accepted as accounting for obstetrical palsies, and that injuries to the skeleton in the shoulder region had long been considered as a cause of this condition. The author regarded as a fact and opposed to prevailing theory that they frequently had palsies of the upper extremity which were not due to actual nerve injury and which might be very severe. Restore the normal motion to the shoulder joint and the paralysis would disappear in the great majority of cases. He expressed the conviction that the usually overlooked posterior and incomplete dislocations of the shoulder would prove to be the key to the solution of the problem in connection with the obscure obstetrical palsies. He was not excluding ruptures of the brachial plexus in obstetrical palsy, but merely maintaining that it probably did not occur in any of his thirteen cases and that it probably was responsible for most of the cases. In six of his nine cases with subluxation the treatment was directed toward restoring normal motion, the first principle of which consisted in restoring the normal relations. In two incomplete reductions of the dislocation much improvement in motion and power was accomplished by the bending down of the acromion anteriorly, which prevented complete reduction and was not recognized at that time. In three others the reduction was complete or practically complete, but the return of motion and power was not yet as good as in the two cases incompletely reduced. In all three of these cases the progress was encouraging. In another case nearly normal motion in the shoulder had been established by exercises without any attempt at reduction of the subluxation which was so mild that it was overlooked when treatment was begun. The theory of shoulder joint origin for most cases could only gain favor by showing better results from treatment. F. La Lange, the German orthopedic surgeon, had adopted the view of the shoulder joint origin for most of these cases of birth paralysis, although the author's paper appeared a year and a half before. The evidence was growing that posterior subluxations of the shoulder were frequently overlooked in these cases. If the dislocation occurred at birth it could not be due to paralysis. If a dislocation of the shoulder in an adult without injury to the nerves could produce a brachial paralysis, which, in the writer's opinion, had been clearly shown to be possible, then a dislocation of the shoulder in the newborn ought to produce a more serious palsy because of the more delicate nature of the nerves and muscles. The occurrence of the dislocation at the time of birth was greatly strengthened by the finding of a bending downward of the anterior portion of the acromion which could only be due to a pressure and could not be accounted for by an injury to the brachial plexus. The same pressure which bent the acromion down pushed the humeral head backwards and downwards. Lange believed that they could not have a subluxation of the shoulder joint, which, in the writer's opinion, was true of adult cases. In them the head of the humerus could not remain resting on the glenoid margin, but must pass far enough over the margin to lock in the dislocated position when the arm came to the side or slipped back into the socket. But in the newborn the causative direct pressure pushed the head back and bent the acromion down in front of it so that this portion of the acromion held it back, resting on the posterior glenoid margin and prevented it from slipping forward into the socket as it would have done had there been no such obstruction. The greatest need now was examination of these shoulders immediately after birth, and this they would now have since attention had been directed to them.

This paper was illustrated by lantern slides.

Arthroplasty with Special Reference to the Use of Animal Membrane.—Dr. William S. Baer of Baltimore, Md., presented this paper in which he first reviewed the various methods that had been employed with the purpose of producing mobility in ankylosed joints. These were *brisement forcé*, arthrolysis, pseudoarthrosis in the neighborhood of the ankylosis, resection, and transplantation of the entire joint. He then reviewed the history of arthroplasty. The results of his work for the past six years which he presented were based on the findings in 52 cases in which chromicized pig's bladder had been used as the transplanted medium, and these cases had been carefully watched from a period

of six months to six years. The advantages which an absorbable membrane had over a muscle flap, a fascia flap, a fascial and fatty flap, and non-absorbable inorganic plates was as follows: (1) The joint would remain as near its normal size and shape as possible owing to the thinness of the material inserted and the minimum amount of resection of bony surfaces that had to be made. The fact that it was perfectly free allowed it to be handled with greater ease, so that their bony modeling could be reduced to a minimum. (2) Simplicity of the operation. The bulk of the material transplanted being very small, the size of the operation was necessarily reduced. Having no pedicle attached, the dissection around the joint was done away with. (3) Stability of the joint. The stability of the joint was not necessarily destroyed, as must be the case in all flap operations where the caput was used as the interposed medium or where its integrity was interfered with by the fascial operation. (4) Infection. There was far less chance of infection owing to the lessened handling of the parts, to the simplicity of the operation and to the fact that the blood supply was less interfered with. (5) The after treatment was less painful. In flap operations, as the formation of a joint was said to be due to the production of hygroma, constant motion must be instituted soon after the operation, which was extremely painful. In a membrane operation absolute rest of the part should be continued for at least three weeks, else the membrane might be torn or displaced, and the new joint formation fail in the making. (6) A normal joint was the result. As the membrane after a period of from sixty to one hundred days was entirely absorbed, there was no foreign substance left continuously in the joint. The membrane to be serviceable for orthoplastic purposes must be thin and flexible. It must be thin enough to necessitate the least possible resection of the joint surfaces and when moist so pliable that it conformed accurately to the configuration of the modeled bones. It must be tenacious enough to withstand disintegration for a period of from sixty to one hundred days, giving time for the fibrous covering to be formed upon the surfaces of the new joint. It must be durable enough to withstand the traumatisms and insults which were forced upon it by the pressure of the ends of the bones. It must be prepared in such a manner as to be absolutely aseptic. The mucosa of the pig's bladder had been found to fulfill the conditions. The writer described the operative technique in arthroplasties of the temporomaxillary articulation, the hip joint, and the knee. The series of cases upon which he employed this procedure numbered 52. The joints operated on were as follows: Four temporomaxillary, 23 hip, 19 knee, 3 phalangeal articulations, 1 ankle, 1 elbow, and 1 radioulnar articulation. If the cases were considered together, irrespective of the joints involved, he had obtained voluntary motion, and painless and useful joint in 71 per cent. of the cases. In the hip and knee he had assumed that if a patient had less than 25 degrees of voluntary painless motion the case should be recorded as a failure. After reviewing in detail the various groups of cases embraced in his series, the writer said that there were certain lessons to be learned from their experience. In tuberculous cases, owing to the nature of the ankylosis, being generally fibrous in character, there was not the necessity of much remodeling of bones. And owing to the fact that the periarticular tissues were generally less affected than in more septic processes tuberculous cases in general gave the best results. Care, however, must be taken that the tuberculous condition had ceased, otherwise a tuberculous condition might be relighted. Generally speaking, tuberculous joints of children should not be operated upon. If bony modeling was undertaken, one interfered with the epiphyseal line, and hence hindered future growth. It was wise, therefore, to delay operation until epiphyseal ossification had taken place. In cases of more acute inflammatory conditions, as those due to gonococcus, it was well to wait some time before operating. His experience indicated waiting one year after the acute onset of the disease before performing orthoplasty. Chronic diseases, as arthritis deformans, which were still active, though subacute, should be avoided. In a former communication early passive motion was advised; this he now believed was a mistake, and was accountable, in a measure, for some of the poor results in the early cases. After the plaster had been removed passive motions should be instituted, followed in a week by active use. Massage, hydrotherapy, and mechanotherapy should then be instituted. The after treatment required patience, skill, and pertinacity, and this should be explained to the patient before operation. In properly selected cases good, serviceable, painless motion could be obtained by membrane arthroplasty in most joints, particularly in the jaw and the hip joint. In the knee joints, fibrous ankylosis of the entire joint, of bony ankylosis of the femoral-patella articulation, with fibrous ankylosis of the femoral-articulation, gave excellent results by this mode of arthroplasty. In true bony ankylosis of the femoral-tibial joints the results were still unsatisfactory, but gave hope of something better with a more extended consideration of the difficulties involved. This paper was illustrated with lantern slides.

Dr. Lewis A. Stimson said he would limit himself to a discussion of only one of the papers read. The subject that Dr. Thomas had discussed was one in which he had been much interested. He had long since learned to recognize the patience, thoroughness, accurate observation, and judicial temperament which Dr. Thomas brought to his work, and that his conclusions must be received with respect and differed from with caution. Certain definite facts about obstetric dislocations occurring in infancy and been acquired, but, alas, some important ones were lacking; any conclusion that was reached must have been reached with the expectation of a possible change in them when those lacking facts shall have been ascertained. Among the ascertained facts concerning the etiology were these: It was known that a great many children were born with paralysis of an upper extremity at birth. It was known that in some of those cases the labor was not always difficult, but that it commonly was. It was known that in some of those cases an injury had been recognized at the time, at the side of the neck, as evidenced by a swelling that was palpable. It was known that in a certain number of cases that point when exposed by an incision showed a definite lesion at the junction of the fifth and sixth cervical cords. In some of these obstetrical paralyses recovery was entire and no evil results were left. On a certain other number, however, more or less extensive results in the form of group paralyses, the Duchenne-Erb paralyses, those of the deltoid, biceps, brachialis anticus, supinator longus, etc., remained. In these latter, according to some observers, notably Fairbanks, there would be found, after a longer or shorter interval, a posterior dislocation. Fairbanks had seen these dislocations in all grades. That was the line of argument that favored the theory that the dislocation was the result of the paralysis, but there were certain gaps in this theory. First, no one had observed such a case continuously from birth. The obstetrician did not notice them, and the cases did not come to the attention of the surgeon, until after a certain length of time. There were a few cases in which it had been alleged that the dislocation originated at birth, but the definite positive observation was lacking. Another difficulty in this theory was that it was extremely difficult or impossible to recognize the mechanical forces producing dislocation in a case of such paralysis. Fairbanks attributed it to the unopposed action of the subscapularis, but there was reason to believe that that muscle also was paralyzed, and even if it was not, it was difficult to see how its contraction would produce the dislocation, for the pull of the muscle was at right angles to the direction in which the head of the humerus must move to reach the position of posterior dislocation. But still one must bear in mind that the ability to detect a causative factor was not proof that it did not exist. So much for the theory of the paralytic origin. He then considered the arguments for a traumatic origin. Here again certain essential facts were lacking. Dr. Thomas had instanced cases of paralysis in adults, due to injuries to nerves in the immediate neighborhood of the joint caused by a dislocation, and he attributed the obstetrical paralyses to the same cause. He argued that the observed condition in the neck, the hematoma about the cervical cords, might be an extension of the lesion in the axilla. But there were no observations to prove such an extension, and it was a very difficult one to accept, especially in the face of observed lacerations of the fifth and sixth cervical cords at the high level. Dr. Stimson said he had great difficulty in understanding any lesion in the axilla so severe as to manifest itself by the appearance of a hematoma in the neck, etc., without evidencing at the same time injury in the axilla. The traumatic theory Dr. Thomas had quoted him as holding, and he had acknowledged that he did hold it, he had put forward many years ago, but only tentatively. When he learned that Dr. Thomas

was coming to speak before the Academy he had hastened to let him know that his opinion had been shaken. They knew that no cases were on record, or cases that had been learned about by inquiry, where displacements had been observed at birth, or, even earlier than the fifth week after birth. That did not mean that such cases had not existed. But it is extremely difficult to believe that a dislocation which was produced by violence received upon the shoulder, a driving force directed backward and depressing the acromonion, it was almost impossible to believe that such a force should not be so marked in its results as certainly to attract the attenion of anyone. Another argument used by Dr. Thomas in favor of the traumatic origin was the frequently observed change in the shape of the acromion and the coracoid, a change claimed to be the effect of the violence which drove the bone back. Dr. Thomas had found the acromion enlarged and depressed and others had found the coracoid lengthened and curved. It seemed to him that there was a more plausible explanation of these changes in the pathological law well established, that the removal of normal pressure from a growing bone was followed by its exaggerated growth and a consequent change in its shape. Dr. Stimson quoted two cases to illustrate that it was the removal of pressure which led to the lengthening of a bone, and he believed that this pathological fact was a far more plausible explanation of the observed change in the acromion and coracoid than violence at birth. In a number of cases the more or less complete reduction of the dislocation had been followed by great functional improvement in the use of the limb, and Dr. Thomas had used this to support his theory, but it might equally well be maintained that the functional improvement was a simple mechanical consequence of the change in the attitude of the limb, a change which gave the forearm a wider range of motion unimpeded by the fact that in one case a similar functional improvement had been obtained by osteotomy at the middle of the shaft of the humerus and outward rotation of the lower segment for about 90 degrees.

Dr. Alfred S. Taylor said that the examination of the shoulders in fifteen new-born babies showed the coracoid and acromion small, rudimentary, and not bendable. The head of the humerus prominent anteriorly, one-half inch in front, so that it could not be pressed back by them. Direct, firm, backward pressure of the head of the humerus when the child was relaxed would cause posterior subluxation, but spontaneous reduction occurred as soon as the pressure was released. With the same pressure, when the child was resisting, no displacement occurred even when considerable force was used. Dissection of the new-born infant's shoulder showed that when the muscles were removed the capsule was so loose as to allow luxation in any direction. Exposure of the glenoid showed it to be a small cartilaginous surface looking forward and outward at an angle of about 45 degrees. It was about 2.5 cm. by 0.6 cm. convex from side to side with a very hollow dimple at its center. This was very different from the adult shape of the glenoid fossa, and would certainly favor dislocation. The head of the humerus was a globular elastic piece of cartilaginous material. The deduction from these facts was that as far as the bones and capsule were concerned the shoulder would tend to dislocate easily in almost any direction, and that the normal relations of the joint were maintained entirely by the balanced action of the muscles surrounding it. Dissection of the shoulders of an infant dead within five days of birth showed that with the skin and deltoid removed and with exposure of the spinatipectoralis major, subscapularis, and latissimus dorsi insertions, direct pressure backward on the head of the humerus caused only slight subluxation, and spontaneous reduction immediately followed cessation of pressure. The spinati could be seen and felt to resist backward displacement. With section of the insertion of the supra and infra-spinatus muscles, internal rotation of the humerus and rather slight backward pressure caused well-marked posterior luxation of the shoulder, which persisted after the pressure was removed. With the spinati divided, pulling the pectoralis major to simulate contraction, caused internal rotation, but no backward displacement of the head of the humerus. Pulling the subscapularis caused internal rotation with slight posterior subluxation. Pulling the latissimus dorsi caused its internal rotation and marked posterior displacement. While the dissection of one set of shoulders could not be conclusive it strongly suggested that the luxation under discussion was brought about by interference with the balance of the muscular activity about the joint and aggravated by the contracture of the unresisted antagonists of the paralyzed muscles. If this were so the luxation should appear somewhat tardily and should become more pronounced with the passage of time. Fairbanks, who had observed a considerable number of cases in England, said that such was the case and this entirely agreed with the results of his observations. He had never seen one of these posterior dislocations under two months of age. Moreover, there were many of these birth palsies which never showed any dislocation at all. Within the last month the speaker had seen four cases varying from four weeks to eighteen months in which there was absolutely no displacement of the shoulder. Concerning the relation of nerve injury to the paralyses and dislocations, it might be interesting to refer to the results of experiments carried out on the cadavers of twenty new-born infants. It was demonstrated that the one important factor in causing the Erb type of birth palsy was forcible separation of the head from the shoulder. This caused stretching of the nerves, and, if the force was sufficient, tearing of the deep cervical fascia, the nerve sheaths with their vessels, and, finally, the nerves themselves. In the living subject these traumatized tissues, infiltrated with blood clots, cicatrized and formed a barrier impassable to the nerve impulses. In vertex presentations with the head delivered and the shoulder caught under the symphysis any attempt to deliver the shoulder by manipulating the head and neck would put the nerves on the stretch and a certain proportion of them would tear. Likewise in breech cases the attempt to deliver the aftercoming head by traction with the fingers hooked over the child's shoulders put the nerves on the stretch. In these palsy cases the muscles paralyzed fell into groups which corresponded very accurately with the motor supply running through the root or roots which had been damaged. It would be strange if an effusion from the torn capsule of the shoulder joint should infiltrate the nerve trunks in the axilla in such fashion as to produce such an effective effect. In a series of 49 operative cases at least forty-five of them showed a cicatricial lesion of the nerves above the clavicle, and this cicatrix did not extend down to the level of the shoulder joint. He had seen a number of cases in which one or more nerves were torn off close to the spine and dislocated an inch or more away and adherent to the neighboring muscle. In almost every case the cicatricial lesion of the nerves could be easily demonstrated. In the few cases in which the lesion could not be found there was evidence that the roots had been pulled from the spinal cord itself and so no extraspinal lesion was present. It might be pertinent to ask what mechanism would cause dislocation of the shoulder in breech cases which furnished nearly half the cases of birth palsy. The paralysis came on at once at its maximum intensity, as should be the case in nerve injury. If the paralysis were due to injury to the shoulder capsule and infiltration of the axilla, the paralysis would appear somewhat tardily and would be progressive as the cicatrix proceeded. Also in this case the muscle groups paralyzed would represent mixed nerve trunks rather than pure root lesions, as was the rule. For these reasons, and especially as the nerve lesion was found in practically every case investigated, whereas the luxation of the shoulder was present in only a portion of the cases, and even then appeared some time after birth, it seemed fair to conclude that the nerve lesion was the essential feature of these cases, while the luxation of the shoulder was secondary and purely incidental.

Dr. T. Turner Thomas of Philadelphia said he knew that he would have to support his position in New York because of the interest in the subject manifested by New York surgeons and the varying positions they had taken. He wished to say that he had always had the greatest respect for Dr. Stimson and his work, and that he had not undertaken to publish anything on dislocations without first consulting his book on fractures and dislocations. In the preparation of his first paper, which discussed these obstetrical palsies, he did not consult him because he did not then appreciate the importance of congenital dislocations of the shoulder in relation to this subject, but he did consult him for his recent paper. He wanted very much to see one of these dislocations at birth before saying that he believed they developed at birth, but he gave up all hope of such an opportunity and concluded to attack the problem from other directions. The general practitioner who attended most confinements had not been taught to suspect the

shoulder joint, where the lesion was very obscure, but to accuse the brachial plexus and to expect that the great majority of cases recover spontaneously, both of which teachings, in his opinion, were decidedly wrong. The physician was not likely, therefore, to call in help immediately, and when he did was likely to bring in a neurologist. Dr. Thomas had no reason to hope that he would ever be called in such a case, so that he had given up waiting. Dr. Taylor and he were extremists on this subject. There was a wide variation even among the supporters of the plexus theory, in the degree of faith placed in a plexus injury. It was shown clearly here in New York. Dr. Whitman, for instance, accepted the theory, but did not apply it in practice. He let the plexus alone and treated only the shoulder joint condition. He reported and demonstrated excellent results here ten or more years ago. In Dr. Thomas' opinion they deserved much more attention than they received. Dr. Taylor went to the other extreme and proved his faith by his operation on the plexus. The only criticism Dr. Thomas offered to his operations was that he ignored the absence of sensory disturbances, although the roots of the plexus were all mixed motor and sensory nerves. He seemed to be the chief successor of Kennedy, who introduced the operation, but who seemed to have dropped out of the discussion. He reported a group of cases, operated on (*Brit. Med. Jour.*) in 1903, but seems not to have published a second paper. It would be interesting to have a second report on his cases. Dr. Thomas appealed for a fair trial of the theory of a shoulder joint origin of these cases. In all his cases in which the arm was permanently crippled he found a posterior subluxation of the shoulder. In those without a dislocation the arm recovered its function completely or almost completely. The shoulder should always be examined carefully at birth and any displacement corrected. It was usually of mild grade and difficult to detect. The best sign was the absence of the normal prominence of the upper end of the humerus in front of the acromion and a slight prominence under the posterior margin of the acromion, where there was normally a slight depression. He referred to a case in which the physician in attendance at birth urged an operation on the plexus at that time. The remarkable improvement which resulted in the next six months without operation caused the father to forbid any other physician to examine the child. Dr. Thomas did examine it when about eight months of age, when the arm was still much crippled, but was far from a completely paralyzed arm, as immediately after birth. He overlooked then a mild posterior displacement which he recognized later. He had the same experience with another of his earliest cases, showing that if, with his keen interest in the dislocations he overlooked them, those not so interested should be much more likely to do so. These cases should be examined by a competent surgeon who was familiar with the normal contour of the shoulder. The frequency with which these dislocations had been overlooked indicates that such familiarity was not very common. Surely the prospects of complete recovery offered by the theory of a shoulder origin for most cases should obtain for it a thorough and fair trial.

Multiple Lupus Vulgaris Involving Skin and Mucous Membranes.—G. Pernet reports the case of a boy, aged 15, with a history of two years' duration. There were numerous patches and foci of lupus vulgaris scattered about the face and limbs, especially the legs. The disease had started on the right arm. The palate and nasopharynx were also involved. The boy was treated with the *x*-rays, and, in addition, tuberculin injections were given, owing to the involvement of the mucous membranes. The multiple lupus vulgaris lesions did not follow measles or other acute exanthem.—*Proceedings of the Royal Society of Medicine.*

Hereditary Blue Sclerotics and Brittle Bones.—E. A. Cockayne reports the case of a female aged one year and ten months who had never walked and who had deep blue sclerotics. A skiagram showed an opacity of the bones less than normal. The infant's father had blue sclerotics and broke both legs at the age of sixteen. Recently he broke his femur and several ribs by falling from his bicycle. His sister had blue sclerotics and broke her ankle by slipping off the bottom step of a staircase. These two were smaller than any of their brothers or sisters. The grandfather was a very small man, had blue sclerotics and had frequently broken his bones.—*Proceedings of the Royal Society of Medicine.*

Miscellany.

The Physician and His Business Expenses.—Sir John Collie enumerates the following as the more important of the usual business expenses of the practitioner in England: Fees for pathological examinations. Drugs. Surgical instruments and medical books. Subscriptions to medical societies. Salaries or fees of assistants. Postage and telephone rental and calls. Accountancy fees. Wages, including board, of any extra domestic servants rendered necessary by the practice. Workmen's compensation and national health insurances. All carriage and motor expenses, including repairs, renewals (which are not capital additions), licenses and insurances of car and man, also depreciation of car. If the physician has an office separate from his home the whole cost of the former must be deducted before his profits can be arrived at. If the physician carries on his profession wholly or in part at his residence, a proportion of the rent (not exceeding two-thirds) rates, taxes, lighting, heating, and repairs must be debited. The proportion of rent deducted will of course correspond to the value of the portion of the house set aside for professional purposes. Bad debts should be estimated and deducted, and also a percentage for depreciation of furniture, etc., of the office and waiting room. Life insurance premiums may be deducted, provided they do not exceed one-sixth of the income. All of these items, with the exception of the depreciation of the car, are proper deductions to make when preparing one's income tax returns, at any rate in England.—*British Medical Journal.*

The Acquisition of Capital.—Sir John Collie points out that it is the duty of every man, even from the time when he commences to practise, to endeavor to save something each year, and as the practice increases this sum, of course, should be larger. Most prudent men who wish to earn an honorable competence and a solid reputation do this. The author strongly urges the physician to go a step further, a step which will make all the difference between that honorable independence which we all hope for, and a hard, unprovided-for old age, which we all dread. The physician should never spend capital. He should never spend the interest of capital. There is no excuse for doing so. It is the provision which he has earmarked, which he is saving for his dependents in the event of his death, and for himself when past work. Assuming his income has not declined, he obviously should not require last year's savings or the interest on these savings, for this year's expenses. He saved last year because he more than met the expenses of that year, for he had a surplus. What he then saved is now capital, and the author wants him to look upon all capital and the interest it brings as a thing apart from his ordinary income and expenditure. In this way only can professional men with small incomes and no pension provide for their dependents and for their declining years. Oliver Wendell Holmes said: "Put not your trust in money, but put your money in trust," and a greater than the poet physician said, with arresting impressiveness, "Whatsoever a man soweth that shall he also reap," which is as true in the conduct of business as it is in ethics. To save money in general practice is, of course, difficult, but it can be done. The essential success is "a clear and steadfast view of the end."—*British Medical Journal.*

THE PRESENT ESTIMATE OF THE VALUE OF RADIUM IN SURGERY.*

BY ROBERT ABBE, M.D.,

NEW YORK,

SENIOR SURGEON TO ST. LUKE'S HOSPITAL.

GENTLEMEN:—I feel deeply the honor as well as the responsibility of addressing you to-day. Your invitation asks me to speak of the present estimate of the efficiency of radium to the medical world, and it would be audacious in me to venture on so serious a subject had I not formed a somewhat definite picture in my own mind of its worth. It is fitting that I should speak to you this year because it is just ten years since I yielded to a request of the Yale Alumni in New Haven after I had one year of experience with this new and almost unknown agent. Certainly after ten years some good result must have been achieved. If not, its usefulness may well be discounted.

In view of the enormously exaggerated newspaper claims of its power to destroy disease, which have justly filled your minds with doubt and disbelief and which it is not in your power to controvert, your committee has asked me to speak the truth on this engrossing theme. Truth is revealed slowly in science—as words spell themselves out letter by letter. The *whole* truth about radium will be written years hence, for we are in the first decade and its importance still grows. Ten years ago Professor Rutherford, who is easily the first authority to-day on the subject, said to me that the physicist then knew about all that was likely to be known about radium and it was the work of the medical profession to see what it would do in their hands. Since then he has issued a new edition of his great work every year or so, old ideas being obsolete, and still finds that it is the newest wonder in science. Is it any marvel that its usefulness cannot be estimated by our present knowledge of its ability to cure? The only regret is that the profession and public have been expecting too much. People who expect too much are *never* happy when they get less than they expect.

We are dealing with a wonder-working mineral unlike any other agent in our hands. While it resembles the energy of the Roentgen ray, it is unlike it in many ways. The output of a small bit of radium powder is a composite force largely electrical, but unlike electricity in any form heretofore known to professional work, it is associated with the extraordinary discharge of infinitely numerous streams of particles each bearing its charge of electricity, some positive, some negative, resulting from the explosions of atoms with a force driving them into tissues with the speed of light. Into Nature's rocks, by the most artful exhibition of scientific detective work, Madame Curie pursued this unknown substance and dragged it forth, a little giant in power, to reveal the hidden mysteries of physical force and touch human interests in the control of some diseases. In itself radium illustrates in concentrated form the universal process of change and decay of matter. Its enormous energy is like incorporated life and its electrons like imprisoned life released.

The first surprise we all felt at seeing a photograph by the Roentgen ray through an opaque body is eclipsed by the photograph made with the same marvellous penetrating power of a tiny pinch of radium confined in a glass tube, photographing through the human body, or a granite bowlder, or some several inches of steel. As it penetrates stone or steel, it moves in undeviating lines. Nothing can deflect its direct movement, or resist the destructive power of its impact. Yet it carries into the tissues also a material force not *destructive*, but a subtle power to help—a *constructive* force—which the keenest study has not yet analyzed or harnessed. This is a *stimulating* force, recognized first in its effect on plant life, and later brought into use to explain some of the phenomena of its influence on tumors.

At this point all argument has to give way to observation. Until we know why cells grow, what innate power resides in living tissue which compels growth and orderly change in living cells, and until we know why the disorderly and exaggerated overgrowth of cells forms life-destroying tumors, we will not be likely to know what the influence is, which is shot into the cells by the atoms of radium which reduces them to orderly growth. One observer may theorize about the known bactericidal power of some rays from radium being responsible for the alteration of tumors; another, that the chemical changes brought about in the delicate protoplasm may alter their growth: another may advance an hypothesis that the even course of cell growth may be due to a balance between a positive and a negative electric charge in each cell which controls its acts, for they seem to respond to electrical affinities, and that the loss of one might permit an unbalanced and inordinate overgrowth, which a due supply of beta rays of radium each carrying a negative charge of electricity might correct. In any case the sophism of Huxley that "theories help us to bear our ignorance of facts" reminds us that one must revert to the habit of observation for the most part if one would make well grounded advances. So let us now drop all blinding sense of wonderment or misleading or distracting theories and argue on facts alone.

Many have lost sight of the first uncontroverted claims of the action of radium in retarding seed growth, or in repressing animal life, as shown by

*An address by request before the Ohio State Medical Association at Columbus, Ohio, May 7, 1914.

the prolongation of the worm stage of radiumized worms while the unradiumized brother and sister worms passed into the chrysalis and succeeding beetle stage completing the cycle by laying eggs which become worms again, while the radiumized worm remain unchanged—a sort of Methuselah; or, again, the irritative spinal meningitis in mice exposed to radium; or, the disappearance of superficial epitheliomas of the face under radium. Were that all that could be claimed it would be a small contribution indeed. Each year, however, has added something to the credit of its utility. Of this it may well be said that, considering the small amount in existence and the few observers, it is amazing that so much can already be claimed. It is as if a hundred scalpels only were in existence in the world instead of a million for ingenious and experienced men to use.

It is not yet known how best to use radium, whether in strong form or dilute, whether in naked form on a varnished surface or confined behind thin or thick metal filters, to hold back some classes of rays, or in the form of emanations. In view then of the confusion of method and the long time needed to attain permanent results by the few cautious observers, it is no wonder that slow progress is being made. Its evolution is not unlike that of the flying machine, only just now beginning to be practically useful.

Perhaps the first unqualified proof of its conquest of disease was in its dissipating the epithelial cancers of the face. Grant that it followed the same efficient action of Roentgen rays demonstrated to the credit of that marvel; grant that surgery had for generations been able to treat successfully these same small growths by cutting them out or burning them out by cautery or chemicals! By these means we have formerly cured the patient—and we still do so—but we never cured the disease—we only removed it. Now comes a new and subtle power which cures the disease, drives back into orderly life the disorderly cells constituting a tumor. We hold our breath in surprise—and rightly so!

A natural question now arises. Is there here a specific action? Is there a selective action against the component cells of a tumor discriminating in favor of those of healthy growth? We answer, yes, and offer proof by several facts. First, consider myeloid sarcomas. A myeloid sarcoma is an overgrowth of the myeloblasts of the bone marrow. As they increase enormously they destroy the calcific bone by pressure or absorption, until all semblance of the bone is gone and is replaced by a pultaceous mass of soft tumor. In the near future the life of the patient may be sacrificed. During the growth of the tumor a correct dose of radium is given, and the cells not only cease growing but retrograde, and permit a reformation of the bone with its original structure and form. We have to assume that the enormous production of marrow cells has been reduced by atrophy and absorption during the cure, or that out of the riotous overgrowth of new weak cells the primitive cells have reassembled and returned to their normal life work. That certainly seems like a selective action against weak cells. Why has the vicious growing tumor halted and begun to retrograde immediately upon the application of a shower of radium rays? All that has been done has been to use beta rays, of which we know little except that each atom carries a charge of negative electricity, and gamma rays with no electrical charge, but a wave stimulation exceeding the speed of light. The effect is not transient but lasting.

The first startling case I had was of a patient part of whose lower jaw was destroyed by a pure myeloid tumor in which the teeth were set as if in jelly. Radium rapidly reduced the mass until gritty bone began to form and the entire jaw was re-established in shape and structure, with teeth solidly embedded, and this has remained as perfect as a normal jaw for ten years. This type of destructive tumor seems to be uniformly and quickly cured by radium. Ten cases have demonstrated this in my hands, some in the upper or lower jaw, others in the long bones. This I would call a specific act of a certain influence discriminating against disordered cell growth, and sparing healthy cells scattered throughout the tumor tissue.

Scores of similar effects could be quoted, but I will speak of only three others. The first was of a man on whose lower eyelid grew a tumor which in a year occupied more than half its breadth, pushed the lid from the eyeball and grew upward from the lid and downward on the cheek, a large purple tumor pronounced sarcoma by microscopic study. It was given expert Roentgen ray treatment twenty times with no benefit. After four hours of radium from a small tube laid upon it, it melted away day by day and was gone in eight weeks. From year to year for eight years I asked many medical men to say on which lid the growth had been. The eyelid had been entirely ungulfed by the disease, but out of the mass there were reassembled the original cells of the skin, of the sharp edges of the lid, of the hair bulbs and follicles, so that hairs grew again on the restored lid. Repeated examination of the microscope slides has led to dispute as to whether to class it epithelioma or sarcoma. Clinically it did not resemble epithelioma. In either case the radium acted as a specific cure.

Again, I ask you to consider a case of the type of round-celled sarcoma of the parietal bone of the skull. During one year the bone had been eaten away and replaced by a tumor of the area of one's palm, resting on the dura and lifting the scalp two inches from it. A section removed for examination showed a round-celled sarcoma. A silver tube with one hundred milligramms of radium was inserted through it in two places and left eight hours in each. The tumor melted away until in three months it was gone, all but the thickness of blotting paper which shows a remnant of the same cells, entirely inert, in the fibrous stroma.

Finally, as showing a definite specific and selective action, one sees a papilloma in any part of the body disappear uniformly after thirty minutes of radium influence. This I have verified more than a hundred times. But the special point I would emphasize is the fact that where, as in the larynx, the vocal cords are buried in masses of papilloma filling the laryngeal space, the tumors disappear and leave normal glistening white vocal cords—the speaking and even fine singing power return. This proves, even more than gross appearance, that the delicate original tissue on which the tumor was built up, and from which it sprang, is not affected by the radium rays which caused the tumor to disappear. A dozen such cases in my hands have shown its infallible action.

One may also assert its specific action in all basal-celled epitheliomas. One may perhaps choose to call it a repressive action which causes every such tumor to retrograde immediately and permanently, in so far as a ten year "cure" may be called permanent.

There is now accumulating also a series of cases

of myoma, uterine fibroids, in which one or two irradiations of the tumor from the uterine cavity have been followed by progressive shrinkage year after year, until the growth was almost wholly gone, as if the disturbed cell reproduction had been corrected, quite like the types just mentioned.

It becomes us now to speak of some contrasting failures in a different type, the sarcoma which are composed of spindle cells sometimes mixed with a few large free cells, springing from and destroying bone very much like the myeloids, but not composed of or containing true myeloplaques. I have vainly endeavored to bring about a retrograde change in these tumors for many years but have made no favorable impression on them, thus far, by radium. Beginning with a spindle-celled tumor of the temporal bone ten years ago, I have failed in this type, in several fair attempts in similar ones of the tibia, femur, and radius, and of some in the soft tissues, as in the popliteal space. I cannot even claim to have retarded or altered their growth; nor has the microscopic or gross appearance of the radiumized areas shown the specific effects of radium work. This is true also of some types of epithelioma of the skin, the squamous-celled type. Indeed, I have come to regard a resisting epithelial cancer as probably of that type before microscopic corroboration is given. The squamous-celled type are prone to invade the nearest lymphatic gland which the basal-celled tumor does not. By this the surgeon will be warned to resort quickly to thorough use of his keenest dissecting skill. Fortunately this type is relatively infrequent. It is evident then that discrimination in using radium is essential, most of all in the choice of cases, if we would bring this efficient agent into repute for its true value.

Yet there is a greater field of work, that of cancer, which must now be approached with all the skill and judgment of ripe experience, which has baffled surgeons of all times and which is only now being touched by the new agents. With the preliminary facts which I have gone over, we are prepared to take the next step forward. First, I ask, has science revealed the nature of cancer in the virulent form which the public and all practitioners know it? It has not. We only know its gross and its microscopic appearance, its course, and its statistics. It has always been classed among malignant diseases, malignant in the sense that it is a life-destroying growth, composed of cells which in the beginning are a part of the normal cells of our body. In the judgment of pathologists a cancer of the uterine cervix begins as an epithelioma of the cervical mucous membrane; that of the stomach as an epithelioma of the follicles of the lining membrane; that of the breast as an epithelioma of the duct follicles; cancer of the rectum originates in the epithelial mucous gland structures.

If we could radiate the disease in its early groups, we could end it. Such facts exist. I have one patient whose cervix curettings showed early invasion of the submucous structure by proliferating epithelium, a typical early cancer in which radium treatment alone has given a cure of nine years. In only one other form of beginning cancer, that of the breast, where it begins as an epithelioma of the nipple, for which surgeons would always advise mammary amputation, have we an opportunity to test the value of radium in the early stage. In six such cases I have caused prompt disappearance of the growth and maintained subsequent health for several years.

During the years of trial I have necessarily tested radium in many of the massive and inoperable types of cancer, hard scirrhus breasts, encephaloid tumors, large fungating rectal cancers, and tongue cancers of all stages. It was right and just to the subject that these should be carefully subjected to test. I may also say that many terrible cases, from a surgical point of view wholly inoperable, have been offered to me by my surgical friends as a challenge which I have rarely refused. So that out of the mass of the history of ten years I can speak in general terms with some precision.

It is no small tribute to radium to say that in one-tenth of these active cancers a retardation can be seen and one-third in time added to the expectation of life. The method of action of radium in cancer does not seem to me to be specific in the sense that it is in the diseases narrated earlier. Ten years ago I satisfied myself that radium kills the cancer cells in the groups nearby it, but within a limited radius, perhaps a quarter of an inch, and that to destroy large masses many tubes must be placed throughout the tumor. In such cases there was always tissue necrosis with more or less toxemia which always passed away safely. In the earliest days of its extreme use I occasionally observed a temperature of 103° to 105°, never serious for more than one to two days. This was followed by excellent repair. Perhaps I have never sufficiently followed up such cases by further attacks on the neighboring tissues, because they have been associated with pre-existing lymphatic disease, which made the task too hopeless. This method of attack is quite like that of Krönig, Bumm, Voight, and others who have given massive doses in uterine cancer to radiumize the gross mass and have felt that far better results were attained than by excision. Experimental work in this field is still being conducted, not without hope.

One practical, and demonstrated gain to surgery is seen in the principle enunciated by Wickham that if all the massive cancer cannot be removed, radium can be successfully applied to the thin shell of disease necessarily left, with the certainty that it will be destroyed. In one patient I was obliged to leave a thin layer of cancer grown to the wall of the carotid artery at its origin which, however, I radiumized *in situ*. Five years of perfect health have gone by with no recurrence. This principle of killing and safely leaving a small remnant of malignant tumor is of the greatest importance to surgery. It applies to every part of the body. Hence the postoperative use of radium promises to be a material advance.

But the most definitely good effect of radium work in these several cancers seems to follow the blocking of all the vessels nourishing the growth by a process of endarteritis. This irritation is of inestimable value in all radium work where high vascularity and active cell growth are present. Nothing so efficient in treating nevi, either capillary or angiomatous, is known to surgery. It effects a delicate blockading of vessels by endarteritis. Nor is this second to the beautiful results of radium in keloids. The true or the false keloid which no surgeon dares to touch with a knife, yields uniformly to the irradiation by radium which induces a soft fibrosis in the regular and active cellular structure, from which the accompanying itching and burning speedily vanish.

Not the least important rôle played by radium is in its special influence in causing retrograde meta-

morphoses in hypertrophic glandular structures like thyroids, lymph adenomas, lymphosarcomas, parotids, etc. This widens the important field of usefulness. I have treated half a hundred goiters of all varieties by radium alone, and have seen complete disappearance in a few and checked the growth in many. The ideal treatment for most troublesome cases is thyroidectomy. Nevertheless there is a large proportion of goiter patients either not greatly annoyed, or unfit for surgery, where radium is applicable.

Every physician feels the sense of helplessness when confronted by advanced cancer of the tongue. Even with thorough surgical extirpation early return of the disease is well-nigh certain. I have been impressed by the temporary improvement in many bad cases after using radium alone and have now adopted the combined extirpation followed by radium with a degree of hope, because of some cases of long freedom where the half tongue was first removed. Several years will be necessary to speak of cures.

It is difficult to know where to draw the pathalogical lines on tumors affected favorably by radium. It would almost seem as if all aberrant cell growths ought to be controlled, if some are, but certainly at present it seems that the myeloid and round-celled sarcomas and all tumors of lymphoid type yield wholly or in part and that basal-celled, but not squamous-celled growths are consistently curable. Tonsil sarcomas, some gliomas, pharyngeal neoplasms all yield some cases to the credit of radium. It is far too early to classify the types.

It is fair to say in conclusion that, stripped of all extravagant claims, radium is an asset of permanent value to surgery in the treatment of those diseases some of them justly called malignant which I have heretofore defined. In the graver form of cancer, which has so long baffled us all, some definite progress has been made as described, but hard research work must yet be done before someone puts his finger on the weak spot in its method of use.

Finally, let me add that one must pardon the occasional outburst of enthusiasm from those who are beginning the use of radium and are startled by its revelations. These are more than offset by the occasional tirades against it either by those who have never used it, or by those who have some other method to exploit. Both these are natural as they are negligible. They do not affect the real truth that as an agent for the relief of human suffering radium has proved to be a weapon of unique value in the surgeon's hands.

13 West Fiftieth Street.

TRICHINOSIS, WITH A REPORT OF CASES.

By MONTGOMERY H. SICARD, M.D.,

NEW YORK.

INSTRUCTOR IN PHYSICAL DIAGNOSIS, CORNELL UNIVERSITY MEDICAL COLLEGE; ADJUNCT ATTENDING PHYSICIAN TO BELLEVUE HOSPITAL; ATTENDING PHYSICIAN TO THE NURSERY AND CHILD'S HOSPITAL.

The *Trichina spiralis* was accidentally discovered in 1860, by Frederick Zenker, in making a routine examination for degenerated muscle fibers in a case of typhoid fever. In man the infection comes from the hog, which in turn has eaten infected offal, trichina-bearing rats, mice, or trichina-bearing meat. The source of contamination is the encapsulated larva, which exists in the muscles of the animal. The infection arises if ham, bologna, pork, sausage, etc., are eaten either uncooked, or cooked insufficiently to destroy the larvæ. About 6 per cent. of pork is infected. Valin observed that boiling ham for 3 hours did not destroy the larvæ in the center of it. H. Williams of Buffalo found trichina in 5.1 per cent. of 505 indiscriminate examinations.

Life History.—After an individual eats infected meat the larvæ are freed by dissolution of their capsules in the gastric secretions, and escape to the duodenum and jejunum where they develop to adult life in about two days, and where impregnation of the female occurs; the females are viviperous, and in turn burrow into the lymphatics of the intestinal wall and reproduce, about 1,500 per female. The embryos wander with the lymph or blood stream to different parts of the body, preferably the striated muscles, and there become encysted larvæ again; this takes about ten days from the time of infection.

Pathology.—Acute intestinal catarrh and mesenteric glandular swelling, and sometimes ulceration of the mucosa are present. Askanazy's experiments with rabbits showed that the embryos are developed in the lymph spaces of the intestinal villi; from there they pass to the mesenteric lymph nodes and thoracic duct, and to the superior vena cava and the heart; embryos have been found in clots in those situations by Staubli, Virchow, and Zenker. In the capillaries they have been seen by Graham. During the growth of the embryo in the muscles (which takes about ten weeks) degenerative changes occur; inflammatory foci form which persist until the eighth week; these foci consist of round cell infiltration, eosinophile cells, and sometimes hyaline degeneration; after a time some of these cells are absorbed and the rest are converted into connective tissue. The encapsulated larvæ may live in the muscles for many years; in the hog they have been observed as long as twenty years, and in man for twelve years. Ordinarily, calcification of the capsules sets in after about a year, and in time they disappear altogether. Frothingham has demonstrated the embryos in the blood stream, and claims that they can break out of the vessels in the liver, pancreas, and brain, and cause local destruction of tissue. Lamb reports five cases in the Presbyterian Hospital, New York, in which parasites were recovered from the blood, and quotes four more from the recent literature of the subject. Parenchymatous degeneration of the liver, myocardium, and kidneys may occur with embolism. Staubli says they never occur in heart muscle, but an autopsy at the Boston City Hospital discovered them in the myocardium, in the liver, and in the cerebrum.

Opie's experiments proved interesting; he found that during the second and third weeks eosinophiles gathered in the mesenteric glands in such numbers as to resemble abscesses. Where eosinophiles form as much as 15 per cent. of the leucocytes, the marrow presents a characteristic appearance, the fat being replaced by myeloid cells, chiefly those having myeloid granulations. In the lung the capillaries are much distended and red cells escape into the alveoli; sometimes fibrin also collects with polymorphonuclear leucocytes, eosinophiles, and epithelium; and sometimes new tissue is formed; eosinophiles are so closely packed that the specimen takes a homogeneous eosin stain. Askanazy showed small hemorrhagic foci in the lungs of rabbits and demonstrated the parasite in the lesion.

Bovaird's two autopsies showed pulmonary infarcts produced by embolism or thrombosis of the pulmonary artery. In the third week trichinæ are easily found in the voluntary muscles. Flury reports a loss of glycogen in the muscles and liver, and says all symptoms are due to poisoning.

Ingestion is in most cases difficult to determine, as it is only by close scrutiny that the parasites can be seen as small white dots resembling miliary tubercles; when ham or pork eating is much indulged in, the people give it but slight attention, and it is often by a number of a family becoming infected that we learn the exact time of infection.

Incubation begins shortly after the ingestion of the parasite, as the latter requires but about two days for its full development after escaping from the capsule.

This period of *invasion* is usually marked by prostration, nausea, vomiting, severe cramp-like abdominal pains in the epigastric and umbilical regions, headache, diarrhea, chilly sensations and a febrile rise. The severity of these symptoms depends on the severity of the infection, that is the number of trichinæ eaten. In some of the cases enumerated later, the invasion was mild, in others the symptoms of invasion continued until the time of admission, which was usually ten days or two weeks after the onset; this is also the period required for the immature parasite to attain maturity, reproduce in the intestine, and for the embryos to reach the muscles of the host. Many times this entire group of symptoms does not exist, consequently the differential diagnosis in the beginning is often difficult. In two of my cases the onset occurred after an exposure to inclement weather, so that chilly sensations, fever, muscular pains, would not be of diagnostic importance except for the time of appearance of pains, which from exposure would be early, while from trichinosis it would be later. An accurate history is often difficult to get. The invasion with headache, high fever, diarrhea, mild abdominal pain, and splenic tumor, closely simulates that of typhoid fever, and it may be several days before we can exclude the latter disease by the appearance of muscle pain, facial edema, eosinophilia, together with an absence of the Widal reaction and the positive blood culture; the onset of trichinosis is, however, usually more acute than that of typhoid fever.

Symptoms in Detail.—There was one case where the onset simulated that of malaria. Simple gastro-enteritis is sometimes the diagnosis, from the severity of the pain, vomiting, and diarrhea. Fever is one of the early symptoms, and is ushered in by chilly sensations sometimes repeated and accompanied by sweating; in many of our hospital cases the fever has existed from ten to fourteen days before admission so that the whole febrile course may be from three to five weeks or even longer. All of our cases showed daily remissions of from two to four degrees, and these remissions were apt to be accompanied by sweating; none of these cases showed the high continuous fever that Bovaird reports. The temperature subsides by lysis. The fever curve is sometimes confused with that of typhoid fever, especially that of the third and fourth weeks, when remissions occur. One case of this series had been treated for typhoid fever for three weeks before admission to the hospital. Zenker, MacCrea, and Fisher have each reported cases of combined trichinosis and typhoid fever.

Vomiting occurs early; it is usually transient, but may be protracted for several days; it is accompanied by abdominal pain, sometimes severe and sometimes, though not very often, by diarrhea; in one case diarrhea and constipation alternated. No parasites were found in any specimen, although looked for conscientiously and repeated examinations were made. Edema usually appears rather early; it is situated in the eyelids, across the bridge of the nose, in the conjunctivæ, and in no way differs from the edema of nephritis; it occurred in ten of the fourteen cases and may have been present in another who had been sick three weeks before admission. MacKenty reports three interesting cases of edema of the glottis, pharynx, and tongue. Thompson reports cases having edema of the ankles and swelling around the knees and elbows. Eye tenderness, photophobia, diplopia, and pain upon motion, were present in one case; conjunctival edema is common. Subjunctival hemorrhages have been frequently seen by W. Gilman Thompson; these hemorrhages lie external to the iris, are apt to be triangular in shape with their bases inward next the iris. W. Gilman Thompson and F. Parker each report a case with edema of the retina and optic neuritis. Kratz observed subcorneal hemorrhage in eight cases during an epidemic of 264 cases occurring in Hedersleben.

Muscular tenderness, stiffness, and pain upon and after motion are supposed to occur in practically all the cases, and are often the complaints for which patients seek relief, in consequence of which they usually apply ten to fourteen days after infection (or after an average of ten days in the present cases). Muscular weakness and prostration are early symptoms. In a number of cases the onset of the pain cannot be elicited; eight of the fourteen cases complained of no pain at all, nor was there any tenderness throughout the course of the disease; two more gave no history of pain, but were tender upon examination; seven had both pain and tenderness. On the other hand tenderness is sometimes very acute. In the case of J. R. H., an intelligent man, muscular pains, tenderness, and edema, developed on the third day and were present upon admission the following day. The localities chosen seem to be the calves, thighs, biceps, and neck, in the order of frequency. Thompson has seen cases with tenderness over the diaphragm and with dyspnea, signifying a probable invasion of that structure by embryos. MacKenty in operating for tuberculous glands of the neck saw minute white spots in the trapezius muscle resembling tubercles; on microscopic examination they proved to be encysted larvæ.

The most characteristic thing in the blood picture is the eosinophilia; it usually begins early and increases rapidly; thus in one of the cases presented it was 5 per cent. on the day of admission, 9 per cent. on the following day, increasing rapidly to 23 per cent. It evidently remains for a considerable time, most of the cases having a high count upon discharge from the hospital. Bartlett, Howard, DaCosta and Schleipp report cases without eosinophilia, while Brown and Bovaird had cases where it was slight during the first month but reached its height during the second month when convalescence was established: Thompson also had cases among his 53 where the maximum was reached after the temperature struck normal. Kerr and Brooks had cases with counts as high as 80 per cent.; the counts sometimes vary considerably from day to day. High eosinophilia (normal being 3 per cent) is

found in other forms of intestinal parasites, notably ankylostoma; also in bronchial asthma, and in various skin diseases. There is usually a moderate leucocytosis; my cases ranged from 14,000 to 21,000 per cubic millimeter, with four cases having no increase. The proportion of eosinophiles does not seem to have any relation to the total number of leucocytes, as one of my cases showed 34 per cent. eosinophiles with a total of 8,000 leucocytes. There is usually a mild secondary anemia.

An eruption resembling that of typhoid occurred in two cases, and Bovaird reported several such cases in his series; the spots cannot be differentiated from enteric spots and only obscure the diagnosis. Erythematous and urticarcial rashes do occur, but I have not seen them; furuncles also occur from which trichinæ may be emptied.

There were no deaths in the present series, but death sometimes does occur, either from exhaustion and inanition, or from pulmonary infarct and pneumonia.

Case I.—H. W., 21 years. Bartender. Frequently ate sandwiches of raw ham and beef; the present is his first attack. Six days before admission he was seized with cramp-like abdominal pains lasting about thirty minutes and relieved by vomiting; following the onset he had considerable headache; two days later pain developed in both calves and he noticed that his face was puffy. Physical examination showed puffiness of the eyelids, stiffness of the muscles of the arms, and tenderness of the muscles of both legs; there was nose bleed on admission. Temperature on admission was 105°; pulse, 112; the temperature followed daily remissions from 3° to 4°, reaching normal after eight days. There was no splenic enlargement. Leucocytes were 20,000, of which 58 per cent. were polymorphonuclears and 35 per cent. were eosinophiles; hemoglobin, 35 per cent.; red cells, 4,300,000. After the first week in hospital, improvement began; pain and soreness decreased, nausea subsided, and puffiness disappeared. Eosinophiles at discharge were 58 per cent.; muscle section, peripheral blood and blood from basilic vein all failed to show trichinæ.

Case II.—J. LeN., 24 years. Domestic. Two weeks before admission she began to have headache, fever, epigastric pain, vomiting, constipation, and weakness; she was accustomed to eat raw ham. Physical examination showed a pale girl, puffy under the eyes, with rapid breathing, rose spots on the abdomen resembling enteric spots, no splenic enlargement; muscles of limbs were tender, and painful upon motion. Temperature 104°, pulse 110, respiration 40. White blood cells, 8,000; polymorphonuclears, 50 per cent.; eosinophiles, 34 per cent., hemoglobin, 80 per cent. Urine had a trace of albumin and a moderate number of hyaline and granular casts. The abdominal pain and vomiting continued for three days; temperature showed daily remissions of 2° or 3° and reached normal on the ninth day in the hospital, or 24 days after onset. Upon discharge, eosinophiles were 60 per cent.

Case III.—J. K., 26 years. Laborer. For two weeks sharp pains in legs upon motion but relieved by rest; pains later in shoulders and back and arms; one week after onset was obliged to go to bed; he had photophobia and edema of the eyelids. Physical examination showed facial edema, subconjunctival hemorrhage on the outer side of each iris, muscular tenderness over the thighs, calves, and biceps, no spleen; urine negative. Leucocytes, 6,300, polymorphonuclears, 74 per cent.; eosinophiles, 10 per cent. Temperature rose gradually to 105°, patient was apathetic, and speech was dull, spleen readily palpable; eosinophiles, 30 per cent. After ten days, in which the temperature ran from 101° to 104° daily, it remained at 101°, and fell in four days more to normal, accompanied by general improvement (three weeks after admission, or five weeks after onset). Eosinophiles on discharge were 27 per cent.

Case IV.—M. G., 24 years. Laborer. Italian. No history obtained. Physical examination; eyelids were edematous, there was no muscular pain nor tenderness. Temperature 101°, fell in three days. Eosinophiles, 19 per cent., rose to 30 per cent. at time of discharge.

Case V.—A. T., 28 years. Butcher. Ate raw beef and pork every day. For three weeks before admission he had nausea and anorexia, but no vomiting or pain. Physical examination showed puffiness of the eyes and face; muscular tenderness over both forearms and in the back of the neck. Temperature 104°, pulse 88, respiration, 24. Eosinophiles, 46 per cent. Temperature fell gradually and reached normal after ten days.

Case VI.—M. R., 24 years. No history of raw meat eating but frequently ate pork. Attack began three weeks before admission with chilly sensations and fever; headache, pains in thighs and arms, diarrhæa, and colicky pains in abdomen. He was treated for typhoid fever and kept on a fluid diet. Physical examination showed loss of nutrition, no spots, no muscular tenderness. Temperature on admission 101° but fell in three days. Eosinophiles, 10 per cent. Urine contained a trace of albumin and a few hyaline and granular casts. Discharged on the sixth day.

Case VII.—J.R.H., 29 years. Four days before admission he suffered from rather severe abdominal pain and cramps, with diarrhea lasting two days, consisting of eight or ten stools a day. After two days his eyes became painful on motion, tender to pressure, and edematous; photophobia and diplopia were present; headache, chilliness, nausea, followed with muscular tenderness in thighs, calves, and back of the neck; muscles were stiff and painful on and after motion. Physical examination; face and eyelids were swollen; muscles were tender upon deep palpation and motion was painful. Urine normal. Temperature varied between 100 and 102°, and reached normal after ten days. Leucocytes, 21,000; polymorphonuclears, 80 per cent.; eosinophiles, 1 per cent.; rose in two days to 33 per cent. Hemoglobin, 80 per cent.; red cells, 5,000,000. Still had muscular pain upon discharge; feces showed no parasites. Two months after discharge eosinophiles were 14 per cent.

Case VIII.—C. K., 28 years. Began two weeks before admission with nausea and vomiting, constipation; frequent doses of castor oil were followed by bloody stools. There was headache, vague pains in the joints and the back, eyes normal. Temperature on admission was 103°, daily remissions followed of 4°, gradually reaching normal after ten days from time of admission or twenty-four days after onset. Blood. Leucocytes, 17,500; eosinophiles, 1 per cent.; and three days after were 17 per cent.; on discharge they were 21 per cent. Muscle section showed trichinæ; stools showed no parasites.

Case IX.—J. R., 23 years. For ten days sharp pains in the left side, moderate cough, fever and chilliness. Physical examination showed pulmonary tuberculosis only, no muscle tenderness; urine contained much indican. Leucocytes, 13,000; eosinophiles, 8 per cent.; no parasites found.

Case X.—H. S., 25 years, carpenter. For two weeks sharp attacks of pain in epigastrium continuing till time of admission; slight fever, headache, and cough; no vomiting, no diarrhea, no cough, no tenderness. For two days only, face and eyes were puffy. Physical examination showed facial edema, edema of conjunctivæ and double conjunctival hemorrhages; spleen doubtful. Skin showed rose spots resembling enteric spots. Temperature 105° normal on the tenth day. Leucocytes, 6,000; polymorphonuclears, 70 per cent.; eosinophiles, 11 per cent.; white cells rose to 19,000; eosinophiles to 13 per cent. No parasites in the stools.

Case XI.—M. G., Turk, 18 years. No history of rare meat. Began one week before admission with headache, pains in the calves and thighs. Physical examination revealed no edema. Spleen was felt, however. Muscular tenderness was present in calves, thighs, and biceps. Temperature 103°, normal in nine days. Muscle section negative.

Case XII.—J. B., ate sausage, sometimes raw. For two weeks before admission fever, abdominal pain, and diarrhea; vomited at outset; only tenderness was in his calves. Physical examination showed nothing but tenderness of the calves. Urine negative. Eosinophiles, 43 per cent. and 53 per cent. Temperature, 100° to 101° for seventeen days; discharged with temperature 100°.

Case XIII.—M. F. Was eating raw bacon. For three days headache and shaking chills; edema of face before admission. Temperature 105°, and remittent for fourteen days. Physical examination showed nothing; Widal reaction negative, no malarial organisms found. Urine negative; eosinophiles, 21 per cent. Muscle section showed only interstitial myositis.

Case XIV.—K. F. Began 13 days before admission; chilly, but no vomiting, no headache; edema of face

was present and constipation. On physical examination a systolic mitral murmur was found. Urine showed a few hyaline and granular casts. Eosinophiles, 48 per cent. Temperature fell second day.

Case XV.—F. B. For eight days headache, no other complaints. Urine negative; eosinophiles, 25 per cent. Temperature 103°, irregular for twelve days.

Recapitulation.—The disease occurs frequently enough to be borne in mind where unclassical symptoms of infection occur, and where the history is indefinite. Six cases occurred in six months in the Second Division of Bellevue Hospital. The embryos develop to adult life in the stomach and intestine in about two days, the larvæ reaching the muscles in ten days after infection; the presence of the parasite in the intestinal tract causes a gastroenteritis of greater or less violence, according to the number of larvæ ingested; the incubation period then is short and the invasion usually though not always is well marked. The temperature is remittent in character, varying from two to four degrees, and continues from one to five weeks, according to severity. These long continued temperatures are not infrequently taken for typhoid fever, though the distinct and marked remissions are not characteristic of the latter disease. A splenic tumor is sometimes present. Muscle pain and tenderness are usually present, though by no means always; facial edema is common, and subconjunctival ecchymosis is present at times; this conjunctival hemorrhage with facial edema makes quite a characteristic appearance. The eosinophiles are usually present in numbers ranging from 15 to 30 per cent., or often higher, but it must be remembered that during the active stage of the disease an increase may not yet have occurred, and it may come on during convalescence. It is difficult to find parasites in the stools, but embryos may be found in the blood stream and the larvæ may be found in muscle section; this, however, is not necessary where eosinophilia exists with a good clinical picture. There is often present a mild albuminuria.

REPORT OF A CASE OF PHLEBITIS OF THE PENIS, SIMULATING EDEMA INDURATUM, COMPLICATING ACUTE GONORRHEA.

By M. ZIGLER, M.D.,

NEW YORK.

INSTRUCTOR IN GENITOURINARY AND VENEREAL DISEASES IN THE POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL, CHIEF OF CLINIC, G.U., LEBANON HOSPITAL, ASSISTANT DERMATOLOGIST, LEBANON HOSPITAL, O.P.D.

The following is the report of a very interesting and unusual case:

A. S., lawyer, referred to my office by Dr. Halpern of Brooklyn, gave a history of gonorrhea two years previously, complicated by seminal vesiculitis.

Present history (Feb. 1, 1913).—Acute gonorrhea of five days' duration. Incubation period two days. Gonococci demonstrated in the discharge. Received only internal medication. Seven days later, *i.e.* on the twelfth day of the disease, the patient began to complain of pain in the region of the corona of the penis. Within twenty-four hours he also developed pain in an area on the right thigh, several inches below the groin, and radiating downward for a considerable distance. In about six hours he noticed that both these painful areas had become swollen and tender to the touch, with a marked prominence of the veins. He said that the first involvement was high up on the thigh. This gradually subsided as the inflammation traveled downward along the anterior and finally upwards along the inner surface of the thigh.

Physical examination of the right thigh demonstrated an inflamed, reddened, and swollen area, about six inches long and three inches wide, beginning about two inches below Poupart's Ligament and extending downward in the mid line of the anterior surface of the thigh. On palpating this area one could feel a number of enlarged and dilated veins which were markedly tender.

Inspection of the penis revealed an almost similar condition, particularly well marked around the dorsal surface. The area of involvement extended backward from the corona, for about an inch and entirely circumvented the penis. There was absolutely no redness, but a markedly indurated swelling, very similar to the edema induratum which occasionally accompanies an initial lesion of syphilis; with this difference however, that on careful palpation, a number of tender veins could be felt in the infiltrated mass.

Treatment.—The patient went to bed for several days with an ice bag to the affected parts. Then returned to his professional duties, using the ice bag at night only. During the second and third week of the phlebitis he used tincture of iodine over the area on his thigh, with apparent benefit and made an uneventful recovery from his phlebitis in five weeks.

As for the diagnosis of gonorrheal phlebitis in this case, one can offer only presumptive evidence. As this patient improved quite rapidly under conservative treatment, and also because of known objection on the part of private patients to any needling of the penis, I could not obtain blood for a gonococcus culture. As no other etiological factor could be discovered to account for the phlebitis and as it appeared on the penis shortly after the onset of an acute attack of gonorrhea, in an otherwise healthy man, I feel that I am justified in believing his phlebitis was a complication of his urethritis of Neisser.

Conclusions.—This case is reported because of the rarity of phlebitis of the penis accompanying acute gonorrhea and to point out the existence of such a complication (I could not find a similar case reported in the literature) and the possibility of its simulating very closely edema induratum and to emphasize the differential points of diagnosis between the two conditions. To recapitulate: The differences are as follows: Gonorrheal phlebitis is exquisitely tender to palpation and quite painful when in contact with clothing, etc., while edema

induratum is usually painless. On careful palpation of the former enlarged veins can be felt. This is not possible with the latter. In the former no initial lesion or ulceration can be demonstrated. While in the latter, on careful search, such can be found somewhere in the folds of the edema. The former is not accompanied by hard glands; the latter after two or three weeks is usually accompanied by its satellite inguinal involvement. In the former no spirochete can be found; in the latter they usually are demonstrable. The former in this case accompanied by phlebitis elsewhere (*i.e.*, on the thigh) while in the latter the further course of the case would show the development of the secondaries of syphilis.

10 East Forty-first Street.

TONSILLECTOMY, ITS INDICATIONS AND CHOICE OF OPERATION.*

By W. H. HUNTINGTON, M.D.,

WASHINGTON, D. C.

OTOLOGIST, LARYNGOLOGIST, AND RHINOLOGIST TO CASUALTY HOSPITAL AND EASTERN DISPENSARY; ASSISTANT LARYNGOLOGIST AND OTOLOGIST, EPISCOPAL EYE, EAR, AND THROAT HOSPITAL; ASSISTANT OPHTHALMOLOGIST, EPISCOPAL EYE, EAR, AND THROAT HOSPITAL; INSTRUCTOR IN LARYNGOLOGY AND OTOLOGY, GEORGE WASHINGTON UNIVERSITY; FIRST LIEUTENANT MEDICAL RESERVE CORPS, U. S. ARMY, WASHINGTON, D. C.

I WILL merely touch briefly on the histology of the tonsil and adenoid. Their structure is lymphatic and of hypoblastic origin. The pharyngeal and the faucial tonsils, like other lymph glands, are a collection of lymph cells enmeshed in a delicate fibrous reticulum. Unlike other lymph glands they are peripheral in their distribution, or better described, they are exposed glands. The pharyngeal tonsil differs from the faucial in that it has no capsule, and is distributed in folds, perpendicularly, on the posterior pharyngeal wall, while the faucial tonsils are encapsulated, and contain many crypts, which run to, or nearly to, the capsule. Both are covered by mucous membrane on their exposed surfaces. Both of these bodies are normally present and have a definite function. They give trouble only when their resistance to invading bacteria has been overcome and they succumb to the unwelcome guests.

Wright, Goodale, and others, in their experiments have come to the conclusion that the bacteria attacking a healthy tonsil do not penetrate the epithelium. The hypothesis offered is that the destruction of the organism is accomplished through a biochemical action, the epithelium throwing out an antagonistic ferment which overcomes the organisms, and if the tone of the epithelium is normal, there is, as Ballenger puts it so aptly, "an equilibrium between immunity and infection. When the cellular tonicity is impaired, the equilibrium between immunity and infection is lost and infection occurs."

Diseases Attributable to the Tonsil and Adenoid.—Locally, we have rhinitis, adenitis, pharyngitis, retropharyngeal abscess, etc. With these there arise very often disturbances of the middle ear and tubular catarrh, due usually to the extension through the Eustachian tube; enlarged cervical glands, Riggs' disease, etc. Authorities are now of the opinion that the tonsil in its diseased state is the portal of entry for various systemic infections, such as rheumatism, endocarditis, tuberculosis, acute nephritis, and chorea. Many pains of obscure origin can undoubtedly be attributed to tonsillar infection. When many other remedies have failed, the removal of the tonsil has brought relief in so many cases that it leaves little doubt that the tonsil is remarkably apt in the distribution of its pernicious wares. Children with diseased tonsils who are unfortunate enough to develop diphtheria are known to have much more severe infections than children with previously healthy tonsils. And even after the subsidence of the clinical symptoms their throats often remain positive for very long periods and they become carriers. Personally I have not seen many cases of diphtheria, but I have asked men who have seen a great deal of it, and they tell me that as far as they can remember they have never seen a case of faucial diphtheria develop in a person who had had the tonsils removed. In a late number of the *Journal of the American Medical Association*, Clause of Berlin states that Alexander of Vienna has reported the significant fact that during a severe epidemic of scarlet fever and measles in Vienna the children whose tonsils had been removed were spared by the epidemic.

The occurence of acute nephritis either during or following an attack of tonsillitis is far from uncommon; in fact, its frequency would probably astound us if we made a careful laboratory and clinical examination of all cases. Bingham in the *Archives of Pediatrics*, December, 1910, reports a case of acute nephritis which followed acute follicular tonsillitis ten days after the beginning of convalescence. Other men have noted and commented upon this complication and it is of sufficient importance to warrant serious consideration. Cheadle of London designates the adenoids and tonsils as the "rheumatic cycle" as applied to children. He considers rheumatism, tonsillitis, chorea, endocarditis, etc., as stages in the cycle. A child with chorea in all probability has rheumatism or will develop it, and children with endocarditis are very likely to give a history of previous rheumatism or chorea, or if not, they very likely will develop one or both of these later on. Rürah says, "chronic heart lesions affecting the valves are nearly always of rheumatic origin." Endocarditis, rheumatism, and chorea in children are seen so often associated with or following one another, and so often a history of diseased tonsils is obtained, as to leave little doubt as to the guilt of the oft indicated tonsil.

The careful examination of children's throats and ears has been repeatedly urged, as a part of the general examination, by such pediatricians as Holt, Jacobi, Koplik, Hutchinson, and others, and undoubtedly many cases that present vague symptoms would be diagnosed positively were such careful examinations always made. Todd of Minneapolis, in the *Journal of the American Medical Association*, August 27, 1910, mentions the fact that neuralgias in the region of the tonsils, side of the head, neck, teeth, gums, or antrum of Highmore, may be and frequently are due to diseased tonsils. When we consider that the tonsil is the largest body in this vicious lymphatic circle of infection, and its frequent irritations, the abundance of infectious organisms that are always present, and its direct drainage into the general circulation, it seems a wonder that we do not all die young.

Indications for Operation.—Briefly we may say that the general indications for operation are as follows: Tonsils should be removed when found in a chronic state of inflammation and with a history

*Read before the Medical Society of the District of Columbia, February 18, 1914.

of repeated attacks of tonsillitis or quinsy. The operation should never be done sooner than a week or ten days following the subsidence of an acute attack. Grosvenor in the *Journal-Lancet*, December 1, 1913, presents a number of illustrations of microscopic sections of removed tonsils, and notes the frequency with which infectious material is found in their substance. The ray fungus was present in 15 per cent. of the cases; the tubercle bacillus in 5 per cent.; and bone tissue and cartilage in three cases.

Nearly twenty years ago there was first forcibly brought to our attention the question of the relation of tonsillitis to articular rheumatism. The German specialists on military hygiene and sanitation were among the first to call attention to this matter, although it had been urged by men in this country prior to that time. Dr. Paul Schichold in February, 1910, reported seventy clinical cases of articular rheumatism, in 75 per cent. of which pus-pockets were found in the tonsils. Guerich, following this line of work not only demonstrated pus in the tonsils of his cases, but reported 25 per cent. permanent cures by "tonsillar treatment." What this treatment was I do not know, but, if it was local treatment or tonsillotomy, I can only say that had he done complete tonsillectomies on these cases he would no doubt have had a much larger percentage of cures to his credit. Schichold also mentions that even cardiac complications, if recent, are favorably influenced by removal of the tonsil. Adenoids should be removed when they are so large as to obstruct proper breathing, when there is a chronic adenitis, and in cases of middle ear disease with obstruction of the tubes.

One or two attacks do not necessarily impair the tonsil to such an extent as to necessitate its removal. But with repeated attacks there are changes in the tissue which impair its normal function. It is then that the tonsil becomes a menace to the general health and should be removed entirely within its capsule. A point that should be emphasized is the fact that a tonsil should not be removed merely on account of its large size; only if there is a history of tonsillitis. Some of the smallest tonsils are the most vicious. A tonsillectomy should always be considered a hospital operation particularly in adults. It is a mistake to view the operation lightly or to stimulate that impression in the laity. True, it is not often that complications arise, but when they do they can be exceedingly unpleasant.

Complications.—Severe hemorrhage does occur occasionally, though not as often as imagined by some. Pneumonia, often of streptococcic origin, is a rather remote complication, but does occur and may cause considerable apprehension on the part of all concerned. It seems rather remarkable to me that it does not occur oftener. Pulmonary infarct, cervical cellulitis, gangrene, and septicemia are some of the other hardly pleasant complications that do occur at times.

Methods of Operation.—The methods in vogue a few years ago of guillotining and punching out the tonsil, did not very generally accomplish the desired result. Many cases suffered with subsequent attacks of tonsillitis and the purpose of the operation was defeated by the proliferation of the remnants of tonsil tissue. It is pretty generally conceded by authorities that when it becomes necessary to remove a tonsil, it should be removed completely, within its capsule. When this is done there can be no return, but occasionally there is an extension of the lingual tonsil upward. These masses of tonsil tissue rarely give any trouble, as they are usually healthy tissue. The poor results from the old method and the ill-advised operations have done much to bring this operation into disrepute among the laity at various times. This is to be greatly deplored as there are few operations that give better results, in well selected cases, and conserve the general health more than this operation.

There are many methods of operation but I think they can be divided into three general classes, with minor modifications as to the instruments and technique adopted to meet the personal taste and physical requirements of the operator: (1) Instrumental dissection and removal, blunt and sharp; (2) instrumental and finger dissection; and (3) finger dissection. Of these three methods the combined finger and instrumental operation seems the most logical.

The armamentarium for this operation is reduced to a minimum and consists of a mouth gag, some form of tonsil knife (my preference being the Douglas), tongue depressor, tenaculum, snare, and a good, fairly long index finger. The technique is as follows, using continuous anesthesia: when the patient is well under, insert the gag, depress the tongue well, so as to put the anterior pillar on the stretch, then with the tonsil knife make the incision at the margin of the anterior pillar, where it leaves the tonsil to insert itself in the tongue. Carry this incision up to the superior commissure. The index finger is then inserted in the incision and the tonsil peeled away from its attachments. When the tonsil is well separated you will often find it hanging by its pedicle free in the throat. It is then grasped with the tenaculum and the snare engaged, and the tonsil removed, taking care not to remove a part of the uvula as well. Gauze may be packed into the fossa for a minute or so to control the venous ooze, and usually on removing the gauze you will find a dry muscular bed. At that time it is well to swab out the fossa with a 50 per cent. solution of iodine in glycerin. The epipharynx is then examined and the adenoids are removed if thought necessary.

I wish to mention here an instrument of merit for the removal of adenoids, namely the LaForce adenotome. With the Lowenberg and various other forceps, the Gottstein curette, and others, the procedure does not seem refined. The tissue frequently is swallowed, sometimes it gets into the larynx, and occasionally strips of mucous membrane are torn from the posterior pharyngeal wall. With the LaForce adenotome, if the mass is a median one, it nearly always can be removed in one bite. The Eustachian eminences are in no danger, and one may be sure that the mass is in the instrument. The blade cutting up and severing the mass at the end of the cut obviates the possibility of stripping the mucous membrane.

The point in favor of the finger in the dissection of the tonsil is this: the capsule has a distant feel, and one can tell immediately whether he is behind the capsule or in the tonsil tissue. A point of very great importance. With the instrumental dissection this is not always possible, for with the hemorrhage the sight is largely obscured, and it is not possible to distinguish the tissue by feeling with the intruments. The so-called friable or rotten tonsils so often spoken of I believe to be in a large percentage of cases tonsils that are broken into or cut

into by the operator at the start. When this occurs, it is almost impossible to get back of the capsule, and one must resort to the punch to remove the mass, and more than likely enough of the tissue is left to give subsequent trouble, particularly if it is in the supratonsillar space.

Post-operative pain in these cases, I believe, can be minimized by reducing the sponging as much as possible so as not to injure the mucous membrane on the posterior wall of the pharynx, and the uvula, which gets very edematous and causes considerable annoyance. As to the hemorrhage, the easiest place to control it is on the table while the patient is still under the anesthetic. The blood supply comes from many small vessels, branches of the facial and lingual; they are the tonsillar, ascending and descending palatine, ascending pharyngeal, and dorsalis linguæ. These vessels supply the tonsils, the tongue, the fauces, and the uvula. There is free anastomosis between them. Occasionally one will see a sharp hemorrhage from one of these vessels, usually a branch of the tonsillar. There are many methods of controlling these hemorrhages and many instruments have been devised for that purpose, but none are really satisfactory and most of them are complicated. The mouth is an exceedingly difficult place to work in and it is very trying to have to ligate a bleeding vessel, and often the ligature comes off when the patient begins to swallow or vomit. Probably the simplest and the most satisfactory way of controlling a bleeding point is to grasp the bleeding vessel, or point of bleeding in a curved clamp, and with a suture of number 2 catgut in a small full curved Kelly needle, whip a couple of sutures over and over the clamp, in the manner the gynecologist treats the stump of the broad ligament. These sutures will hold.

The after-treatment consists of liquids and simple cleansing mouth washes, catharsis, and swabbing of the fossa the day after the operation with an iodine mixture. Swallowing is pretty painful for a few days in adults; children seldom complain after the first day. The white membranous-looking lymph patches remain in the throat for about ten days or a week, at the end of which time the throat is usually well. Patients should stay quietly in bed for at least three days.

In regard to this operation upon adults, I can say with feeling that it is far from being a pleasurable event. Anyone who has done many tonsillectomies on adults must have noticed the extreme exhaustion, both mental and physical, which follows this operation. It is out of all proportion to the amount of trauma induced, and it is the writer's opinion that it is due to shock, both psychical and traumatic. Since Crile's theories have been advanced and substantiated, I have been wondering why his "anoci-association" operation could not be applied to these cases I speak of. I have done this on several cases with more than satisfactory results. If possible I send the patients into the hospital about two hours before I expect to operate. They receive a hypodermic injection of morphine about half an hour before they go to the operating room. The anesthetic is started with nitrous oxide and switched to ether when the patient is under. The pillars of the fauces are well infiltrated with a 1 per cent. solution of novocaine and 1/400 adrenalin, when I proceed in the usual way with the remainder of the operation. When the tonsils are removed and the fossæ are dry I inject a solution of quinine and urea hydrochloride in the strength of ¼ per cent. As a rule there has been little or no pain for two or three days and the general weakness which so often lasts for a week or ten days is materially reduced.

I have not had enough adult cases to arrive at a definite conclusion, but I am certainly satisfied that the patient's postoperative condition is much more comfortable under this procedure than it is without the use of these nerve-blocking solutions. It would be much more satisfactory if we were able to use nitrous oxide exclusively, but unfortunately I am afraid that it would not be satisfactory if possible, but I propose to try it at some subsequent time.

BACILLUS COLI INFECTIONS IN INFANCY AND EARLY LIFE.*

By W. MORGAN HARTSHORN, M.D.,

NEW YORK.

ASSISTANT PEDIATRICIAN THE ROOSEVELT HOSPITAL; ATTENDING PHYSICIAN SEA SIDE HOSPITAL, ST. JOHN'S GUILD.

It is my purpose to discuss briefly some of the diseases of infancy and childhood which are caused by the *Bacillus coli*.

1. First in consideration are infections of the brain. Although many textbooks mention the *Bacillus coli* as an etiological factor in meningitis, yet there are few authentic cases reported. Smith of London has collected 32 cases, in only nine of which the colon bacillus was found in pure culture. Of these Holt reported two. To this list may be added one case which Dr. Nicoll has observed and one case which occurred in my service at the Nursery and Child's Hospital several years ago. Dr. Zinsser identified the organism obtained from the spinal fluid as a colon bacillus.

In these cases, which were mostly all young babies, the condition was secondary to inflammation of the intestinal tract, navel, or bladder, otitis media, or spina bifida. Smith concludes that it may be either serous or suppurative. The symptoms are the same as of other forms of meningitis; the prognosis is not invariably fatal.

2. In the respiratory tract the *Bacillus coli* is rarely the only cause of inflammatory processes. It has been found in pure culture in the sputum of patients suffering from pneumonia, according to a case reported by Meara and Niles. Pearson, in the *British Medical Journal* of 1909, reports a case of empyema following a pleurisy and bronchiectases in a boy of seven years. The *Bacillus coli* was found in pure culture in the discharge.

Schroter and Weinberger report several cases of bronchopneumonia caused by this organism.

At the Rockefeller Institute and at the Research Laboratory of the Board of Health there were no case records of pneumonia caused by the *Bacillus coli* alone.

3. In hemorrhagic septicemia of the new-born, or Winckel's disease, a generalized colon bacillus infection has been found. This disease is characterized by marked prostration, vomiting and diarrhea, cyanosis, intense general icterus. The urine, which is passed frequently, is small in amount, smoky in color, and contains hemoglobin. There is usually a fatal termination. In six cases reported by Wolcyznski the infection was supposed to have been conveyed by infected spring water used for cleansing the mouth.

*Read before the New York Academy of Medicine, May 25, 1914.

4. Dr. Anna Williams has reported several cases of acute catarrhal conjunctivitis in which a colon bacillus was found in nearly pure culture.

5. In diseases of the intestinal tract it seems useless to try to discriminate between the *Bacillus coli* and the many associated organisms of the colon group. It has not been proved that the colon bacillus, *per se*, is responsible for the many forms of intestinal disturbances. With the possible exception of that condition known as the intestinal infantilism of Herter and of a brief period in the new-born, the *Bacillus coli* is always present in the intestinal tract. If the body resistance be lowered or if there be an abrasion of the mucous membrane, this organism may prove a source of great danger to the individual.

Nuttall and Thierfelder, from their experiments upon guinea-pigs removed by cesarean section and fed upon sterile food, concluded that intestinal bacteria were not essential to normal nutrition. On the other hand, Schotelius found that chickens fed upon sterile food were retarded in development and showed normal growth only when given food containing bacteria. Leven found that some animals in the Arctic region have no bacteria in the intestinal tract. Herter says that these experiments and findings are, indeed, interesting, but fail to apply to the human organism. He believes that the importance of this class of bacteria lies in their capacity for checking the development of organisms capable of doing harm.

It is not within the province of this paper to discuss the many allied organisms of this group which are held accountable for the severe forms of dysentery found in infants and young children. As Zinsser says: "Whereas, the *Bacillus coli* may aggravate morbid processes by the formation of gas, in an excessive carbohydrate diet, they do not of themselves take part in actual putrefactive processes In most intestinal diseases they actually play but a secondary part."

6. Finally, there is a most interesting group of cases resulting from an infection of the urinary tract by the *Bacillus coli*.

In children this condition is most common during the first two years of life and the majority of cases are in girls. Thomson reports 79 per cent. in girls, Goffert 90 per cent., and Morse 60 per cent. This may be due to the anatomical fact that the short wide urethra of the female is only one-fifth as long as the male urethra and may easily become infected from soiled genitals.

The modes of infection are: (1) Descending by the blood through the kidneys; (2) ascending through the urethra; (3) transparietal, or by contiguity through some lesion of the intestinal mucous membrane. As Morse says: "The mode of infection is not always the same; in girls it may be ascending, in boys transparietal, while in both sexes occasionally it may be hematogenous."

Varieties. — Bacilluria. — Characterized by the presence of the *Bacillus coli* in a urine which is highly acid. There may be a lack of all constitutional symptoms. Sometimes there is enuresis and a marked anemia.

Pyelitis.—Involvement of the pelvis of the kidney, accompanied by marked constitutional symptoms, often associated with inflammations of the intestinal tract, large or small amounts of pus in an acid urine, high or low fever of the remittent type, protracted course.

Suppurative Pyelonephritis.—The most severe form of this infection, with multiple abscesses in the kidney, pus in the urine, more marked constitutional symptoms, chills and fever, recovery rare.

The mortality, exclusive of bacilluria, is about 10 per cent.

These conditions doubtless explain many cases of obscure high fever which formerly were associated with malaria or typhoid.

Treatment.—Mild cases recover with little or no medication. As a rule, however, the treatment must be continued a long time, as the condition has a tendency to recur. A diet suitable for increasing fluids should be given.

Potassium citrate may be given in increasing doses, 30 to 180 grains a day. Sodium phosphate is recommended as a laxative.

Hexamethylenamine, 6 to 60 grains a day, with sodium benzoate. For the liberation of formaldehyde the urine must be acid. For this purpose hydrochloric acid may also be used. The dosage must be very small at first, and the child watched carefully for any sign of kidney irritation, albumin or blood in the urine.

Concerning the utility of vaccines reports differ greatly. Thomson thinks that they may do good in acute but not in chronic cases. Morse believes that vaccines do not accomplish much. Freeman has found that vaccines in acute conditions affect the constitutional symptoms favorably, but do not inhibit the growth of bacteria. He has been as successful with commercial as with autogenous vaccines. Dosage 10 to 100 million at four or five-day intervals.

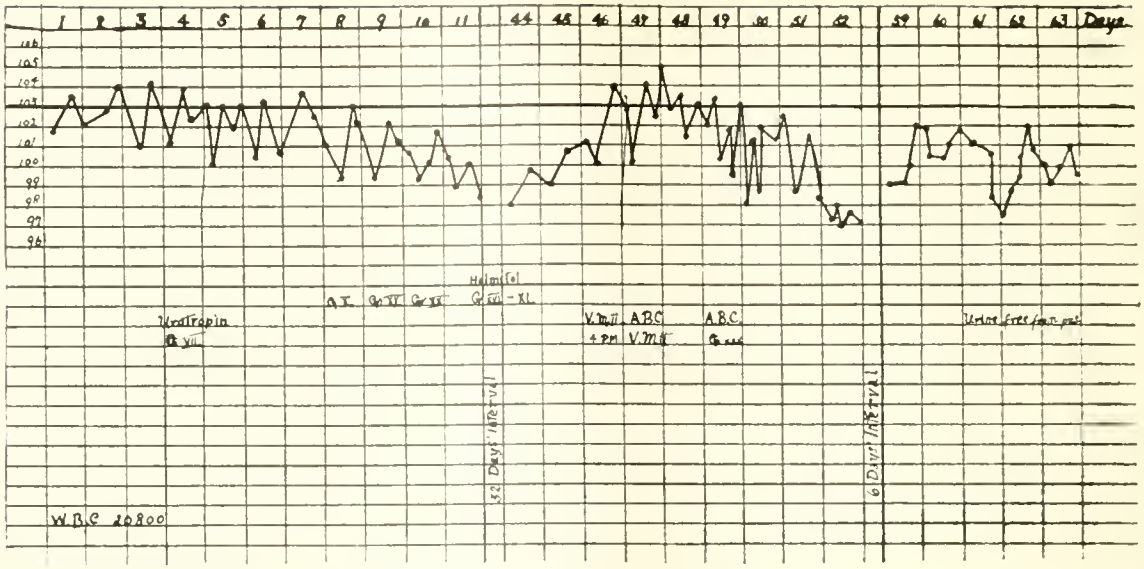
The accompanying charts illustrate (1) the protracted course of pyelitis, and (2) the unsatisfactory results of treatment:

Case I.—A. R., 20 months; female. Under observation 71 days. When seen with the attending physician the child had been ill for one week without marked constitutional symptoms. Temperature ranged from 101° in the morning to 104° in the afternoon. Physical examination was negative. Urinary examination was advised, and the urine was found to contain a large amount of pus. Blood examination showed a leucocytosis, 20,800. The patient was given urotropin in increasing doses, starting with 1 grain, which medication was continued for over a month, the daily dose amounting to 30 grains. At this time there were only a few pus cells found in the urine. During the next 32 days this treatment was alternated with the A. B. C. mixture in daily doses of 33 grains, the temperature ranging from normal to 99° and 100° in the afternoons. At the end of this period there was an exacerbation of the attack, temperature ranging from 100° to 104° in the afternoons. The specimens of urine contained a large amount of pus and bacteria. Vaccines in doses of 10,000,000 daily were used upon two occasions. Their use was followed by increased temperature and marked constitutional symptoms, so that they were discontinued.

The temperature fell to normal at the end of a week, and continued normal for six days, when there was a second exacerbation, which, however, lasted for only six days, the highest evening temperature being 102°. The amount of pus in the urine was small. In the meantime the child had gained over a pound in weight. The mother was advised to discontinue taking the temperature and to send the child to the country.

Case II.—J. H. Six months. Male. Under observation for over 100 days. Chief complaint upon admission was vomiting and diarrhea; duration eight days. Family history negative. Physical examination showed a poorly nourished child with marked signs of rachitis. There was a slight stiffness of the neck and a tendency to opisthotonos. Two weeks after admission a condition of tetany developed which continued for over two months. There was no Kernig sign and lumbar puncture was negative. The urine was found to contain a large amount of pus and bacteria.

Soon after admission the child was given potassium

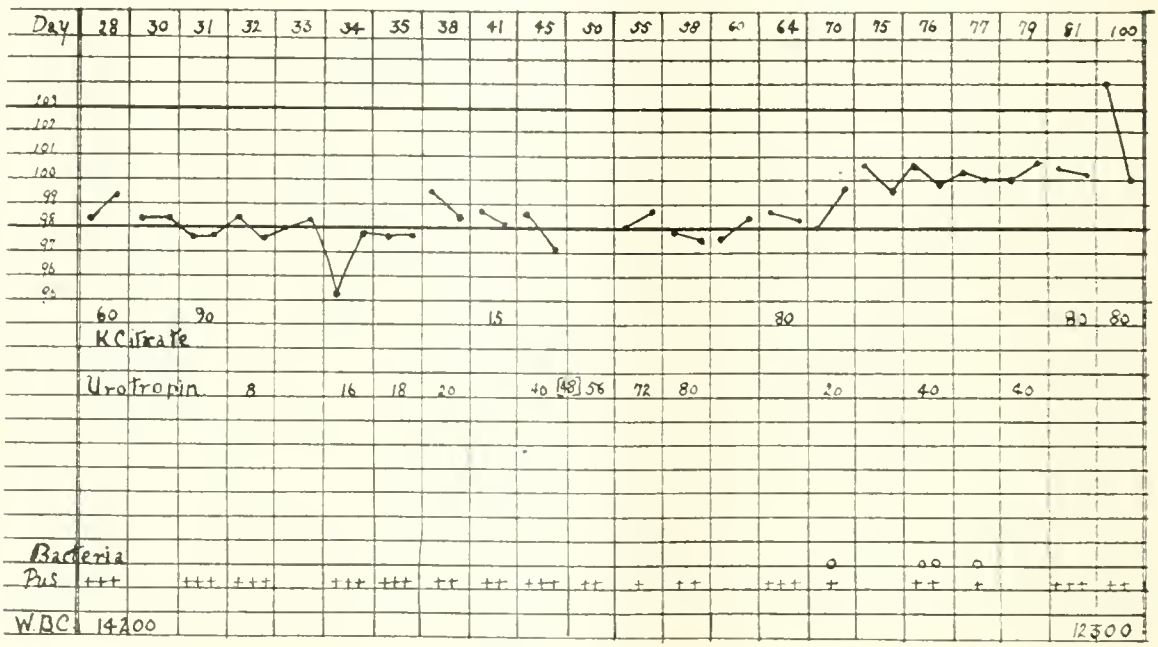


CASE. I.—PYELITIS TEMPERATURE CHART.

citrate, 60 grains a day. This was continued for eight days, and as there was no diminution of the amount of pus and bacteria in the urine the patient was then given urotropin with sodium benzoate, 1 grain of each, 8 grains a day. This was continued for three days, the temperature during this period being subnormal. The urotropin was increased to 16 grains a day and the next day was increased to 18 grains without any effect on the amount of pus or of bacteria. Three days later it was increased to 20 grains. As the pus in the urine had diminished somewhat, potassium citrate was again given, 15 grains p.d. This was discontinued after four days, and urotropin in 40-grain doses was given; increased to 80 grains a day during the following ten days. At this point the amount of pus diminished perceptibly and there was no bacteria in the urine. Four days later both the pus and the bacteria appeared in considerable amounts, and potassium citrate was again given in 80-grain doses. Six days later the urotropin was continued in 20-grain doses. This time there were no bacteria, and the urotropin was increased to 40-grain doses four days later. This was discontinued and potassium citrate was given. Three days later pus and bacteria again appeared in the urine. Potassium citrate was given in 40-grain doses. This was continued for four days. Ten days later, as there was a large amount of pus and bacteria, urotropin was given in 40-grain doses with dilute HCl. The amount of pus and bacteria diminished considerably, but unfortunately at this time the child developed a nasal diphtheria and was transferred to the Hospital for Contagious Diseases.

In conclusion the following observations should be emphasized:

1. In children the *Bacillus coli* may invade the nervous system, causing a meningitis indeterminable clinically from other forms.
2. It has been found in pure culture in diseases of the respiratory tract.
3. It may produce a septicemia, as is found in Winckle's disease and other reported conditions.
4. It has been found in acute catarrhal conjunctivitis in children.
5. It doubtless acts with other organisms of its group in diseases of the intestinal tract.
6. In the genitourinary tract the *Bacillus coli* may be the cause of enuresis, cystitis, pyelitis, and pyelonephritis, these conditions accounting for many of the previously unexplained high temperatures with severe constitutional symptoms.
7. As the course of a pyelitis is frequently protracted and as there are often exacerbations of



CASE II.—PYELITIS.

symptoms after apparent cure, the treatment must be persistent and should be continued until the urinary findings are normal.

8. The most satisfactory treatment appears to be in the use of alkalies or in the guarded use of hexamethylenamine in increasing doses.

9. The vaccine treatment of pyelitis should be considered especially in obstinate cases and when other methods are not successful.

50 CENTRAL PARK WEST.

ULCUS CRURIS INVETERATUM.

BY WILLIAM P. CUNNINGHAM, A.M., M.D.,

NEW YORK.

ASSISTANT PHYSICIAN HARLEM HOSPITAL, DERMATOLOGICAL DEPARTMENT; CLINICAL ASSISTANT NEW YORK SKIN AND CANCER HOSPITAL.

IN this wonderful day of triumphant serology, with its dazzling array of antibodies, antigens, amboceptors, complements, precipitins, agglutinins, sera, antisera, and vaccines, digging to the depths of the causes of things, and fighting in the very stream of life the microscopic agents of destruction, how pitifully sordid, dull, and commonplace will be the discussion of such a subject as chronic ulcer of the leg. It would appear that the last word must have been uttered on this tiresome topic ages ago. And yet it would also appear that the *right* word had not been uttered or appreciated, for like Tennyson's brook it may be said of this lesion "that men may come and men may go but I run on forever." It is fair to assert that every sort of expedient, rational, irrational, deductive, and empirical, medical and surgical, has been exhausted on this Gibraltar of pathological stubbornness, and yet as far as general results are concerned, we are just about where we started. Yet the subject, passé, ennuyant, and repellant as it may be, is of great importance to the general practitioner, because, as the late Lewis A. Sayre declared when I was a student, "more reputation has been won or lost by the young physician in treating ulcer of the leg than in any other way." Literally true or not, this opinion of a very able man illustrates the proper attitude to assume toward what is ordinarily considered a very thankless task. The condition is very common, very distressing, and very resistant. Here is a combination of incentives to arouse all our fighting blood, instead of a pusillanimous impulse to flee when we are confronted with the problem. There is hardly in the whole range of applied therapeutics an analogous situation. Other rebellious processes goad us to commensurate activity. We set our jaws and try on, and forever on. The severer the test the more determined is our response. And we are rewarded repeatedly for our grit and perseverence. But when we are brought face to face with an ulcus cruris, we are seized with an uncontrollable panic and turn tail and run in an utterly shameless manner. We are hopeless from the start and wish that the whirl of fortune had afflicted some rival with the unwelcome visitation. All our knowledge of pathology, of local circulatory disturbance, of secondary infection, of the laws of physics, seems to vanish in the wave of imbecility that sweeps over us when we are expected to apply it to the business in hand. There is nothing obscure about the cause or the condition in leg ulcer. They are appreciable to the primer class in pathology. There does not appear a single adequate reason why the so obviously simple should be so absurdly disconcerting. Yet a reason there must be, adequate or inadequate. This can be nothing else than the constant failure to effect a cure. And this can be due to nothing else than misdirected effort. This is not intended to be a sweeping criticism and condemnation of everything hitherto attempted. Far from it! Somewhere in the monument of monographs erected to this amazing anomaly, will be found imbedded the touchstone clarifying the whole situation. There is no doubt in the world that these rebellious lesions are occasionally cured. But so many clinicians have claimed results from methods subsequently shown to be unfruitful that we are beset by uncertainty and suspicion. We try and fail. We try again and fail. About the time that we begin to lose confidence in ourselves the patient has reached the same conclusion. The issue is inevitable.

It is conceded that no intelligent effort can be made without a correct diagnosis. In these days of the liberal dissemination of syphilis through all classes of the community this is not the easiest object to attain. There are many complicating and distracting factors, that either lead us utterly astray, or balk us of complete illumination. Ulcer of the leg due to other causes is to be differentiated from luetic ulcer. This is of commanding importance because one might treat a specific ulcer with misguided perseverance along the lines laid down for the non-specific sort, and would not get a result in a score of years. Nothing but the antiluetic remedies will touch it. How is the differentiation to be made? The Wassermann, if available, may determine it at once. But one must not forget that there is a possibility of error here, as shall be shown later on. If the Wassermann cannot be em-

ployed, the characters of the lesion must be depended on to guide our judgment. Certain features are said to be distinctive of luetic ulcerations. The sides are punched out, neither sloping nor undermined. The base is sloughy, and exudes an offensive discharge. There is very little surrounding inflammatory infiltration. The shape is round, nephroid, magnetoid, or serpiginous. The last term applies to that peculiar fluted edge caused by the intersection of several circles, the included lines being lost in the ulcerous excavation. Pain is remarkable by its absence. If a reliable history is procurable (a marvel notoriously rare), it will transpire that the first manifestations of the local disturbance was the formation of a doughy mass in the subcutaneous tissue. This gradually protruded under the strained and empurpling skin until there was a solution of continuity, whereupon the center sloughed out leaving a clean cut pit of even base and perpendicular sides with little encircling inflammation. In a general way the round lesion would resemble the hole made by an apple corer. It is indubitable that such a history and such a lesion would need no confirmation from the laboratory. But our course is not always as smooth as that. Histories are untrustworthy, and the local condition owing to duration, irritation, situation, and ill-directed medication, may lack all of the enumerated characteristics. There may be pain and quite pronounced pain at that if the patient be of the neurasthenic sort, or if the lesion be exposed to pressure or friction. Secondary infection may contribute to the same result as well as to the obliteration of another distinguishing sign, by the development of an inflammatory areola. To reduce this to concrete form, a lesion over a malleolus or on the posterior border of the os calcis may be accompanied by very severe pain because of the pressure of the shoe and the constant disturbance of the tissues in walking. Want of cleanliness, especially in the care of the feet, will often bring about the aggravation of mixed infection. It is further predicated of luetic ulcerations that they are prone to invade the upper half of the leg, leaving the lower half free to the ravages of the varicose variety. This is true in great measure, but is far from being invariably true. The proposition might be more satisfactorily stated another way, to wit, that ulcerations involving the upper half of the leg are most likely luetic. Those involving the lower half may be of either etiology. The configuration may be robbed of its identity by the circumstances already mentioned. If the fluted edge persists only one opinion is tenable. But if it is hewn away by the march of secondary infection, there may be some perplexity. The circular outline may be replaced by a perfect parallelogram. This is unusual but must be reckoned with because of its occasional occurrence. I saw a lesion extending from the os calcis several inches up the back of the leg and maintaining an even inch in width all the way. The angles were all right angles. The patient was elderly, and had varicose veins, and hence the original diagnosis had been varicose ulcer. This brings us to another consideration that is frequently overlooked. There is no reason why a syphilitic should not have varicose veins, and consequently a varicose ulcer. We are ready to ascribe every abnormality in such a person to his infection, while it is perfectly obvious that he may acquire diseases absolutely unconnected therewith. Therefore when the laboratory returns a plus Wassermann one must not always consider the incident closed. One may find that the indicated treatment (be it salvarsan, mercury, or iodide of potassium) will not bring the case to a satisfactory termination. Then it will be necessary to look to other possible factors in the causation, and eliminate or neutralize them. Epitheliomatous degeneration in the margin of an old luetic ulcer will prevent the full response to specific medication. This is not common, but it is commoner than we are apt to suspect. The rolled, pearly border indicative of epithelioma is not immediately in evidence. Gradually, however, the character of the border will undergo a change. It will become denser, firmer, and cordlike. It will give the impression that the activity of the process has been transferred to it. It will force itself on our observation as something distinctly individualized and apart from the included excavation. A biopsy at this point will disclose the peculiar pearls, cell-nests, or globes of cancerous degeneration. Operation if the lesion is not too extensive with intensive antiluetic treatment to control the underlying etiological element is the only course to follow. If ablation cannot be safely accomplished the limb should be amputated. In such a situation the complication has assumed dominant importance, and the original disease is subordinated as a complication. Temporizing and palliating are now entirely out of order. Free-hand surgery is the only agent worth a moment's consideration.

Epithelioma disposed of, let us reflect again that the mechanical difficulties producing venous stasis in the lower extremities are just as liable to occur in the man with a positive Wassermann as in the man without, and that after we have met the specific infection in the latest approved scientific manner, our disappointment will be keen unless we employ the measures indicated in the ordinary varicose condition. Tuberculous ulcerations interject another element of uncertainty into the differential diagnosis. These are rather uncommon on the lower limbs, and their occurrence is attributable to extreme degrees of erythema induratum. Ordinarily this tuberculoma manifests itself in the formation of several nodules in the calf of both legs, subsequently undergoing molecular disintegration with absorption, or superficial ulceration with gradual retrogression and cicatrization. If these ulcerations adhere to type and remain on the back of the limb there may be little difficulty in identifying them. But sometimes they appear on the tibial aspect, and are irritated by all-advised and meddlesome medication. Then they are obscured by the adventitious elements superadded. Pain is not a constant accompaniment of erythema induratum, but may exist, and when associated with a slowly spreading ulceration (or several of them) in an area of brawny infiltration the probability of confounding it with the lesions of a sagging venous plexus is markedly enhanced. Attention to the history may elicit illuminating evidence. Involvement of the lungs will be highly suggestive. But the caution administered in discussing luetic lesions will not be amiss in this connection. Every pathological condition in a tubercular subject is not necessarily tuberculous. There may be independent regional disturbances of circulation. Treatment of the general condition will not suffice for these. We will assume now that we have eliminated all possible sources of error and that we are dealing with a plain ordinary old varicose or parenchymatous ulcer of the leg. It has existed for several

years; perhaps for a generation. It presents a picture familiar to every physician who has made abortive attempts to cure it. The repulsive discoloration of the turgid tissues, black, brown, purple and coppery red, the yawning gap sunk deep in their midst, with rigid edges, sloping craggy sides, and base of gray resistant granulations, resembling some miniature valley of desolation, in a blighted lava zone; above the bloated convolutions of englutted veins; encircling all the puffy pasty bluish hue of collateral edema; this combination of unsightly features is difficult to parallel except in swift advancing mordant cancer. The amazing thing about such lesions is that they will persist year after year, with steadily encroaching border, steadily increasing pain and steadily augmenting disability, and yet never seem to threaten life save by the astonishingly remote contingency of secondary malignancy. There is rarely a complicating phlebitis, rarely a systemic infection. The same amount of irritation sustained by any other part of the body would almost positively cause a carcinoma. And still further confounding to our sense of fitness is the circumstance that varicose ulcers are commonest in patients within the cancer term. And as if to emphasize the remarkable exemption of these conditions from malignant degeneration, its occasional occurrence has created some excitement and the adoption of a new title to commemorate the discoverer.

The impression might be gathered from the tenor of this paper that varicose ulcer was well-nigh incurable. That would be a misconstruction of my meaning. It is not incurable under favoring circumstances and intelligent manipulation. Favoring circumstances are the willingness and the ability of the patient to obey instructions. Some patients have no resolution, and some are driven by poverty to damaging disobedience. Here is a favorable opportunity to advance another reason for the nonsuccess of so many practitioners in managing this stubborn affliction. It is a fact that most of the cases occur in poor people. This is in the very nature of things. People of means are not compelled to do the arduous work of their less fortunate brethren. If gravity congestions are imminent in the lower limbs precautionary measures can be taken to forestall them. Such people can rest, can easily obtain appropriate appliances and be guided by solicitous advisers. Neglect, such a potent factor in the ailments of the poor, is inoperative here. So it obtains that pretty nearly all the cases are in a class who can reimburse the physician very meagerly for his ministrations. It is human to fall short of an intense enthusiasm in approaching such a situation. The stimulation of adequate recompense is lacking to arouse the energy necessary for the successful prosecution of any important project, indifferent attention is the inevitable consequence, and indifferent results the inevitable issue. This may rub our pseudohumanitarianism on the raw, but it is absolutely true. We may be very much occupied with works of charity, but our efforts in its sweet service will not be attendant with such a concentration of purpose as when we are reaching out for the flesh pots of Egypt.

However, we may be able to interest the younger men in the relief of these unfortunates, with the assurance that much repute if few shekels will be the reward of perseverence. Of course this will not appeal to those lofty spirits who aspire to be specialists without the preliminary drudgery of being capable physicians. Conceding that some earnest men are ready to pursue the subject to the end how shall we determine adequate ways and means?

First and foremost, be it remembered that ulcus cruris is a dynamic condition caused by the pull of gravitation on an engorged venous system. In the prone position both causative factors cease to operate. The pull of gravitation is removed and the blood flows out of the distended vessels. Therefore, the two principles of rational treatment are to disgorge the veins and neutralize the force of gravity. The broken down tissue is not the disease. It is only the effect of it. This is too often lost sight of in empirical attempts to cure. If the circulatory derangement can be adjusted the sequelæ will disappear as a matter of course. Hence the utter and childish nonsense of trying to close up the hole by agents supposed to favor granulation and cicatrization. If by any chance we should work such a miracle it would promptly cave in again on the suspension of treatment. So it is that the long array of salves and powders and lotions that have been recommended for their prompt reconstructive action on the ulceration is *a priori* absolutely valueless. Experience sustains the correctness of this deduction. Scarlet red, ichthyol, thymol iodide, zinc oxide, ammoniated mercury, boric acid, trypsin, etc., are individually and collectively about as effective as so much distilled water. The partial results sometimes noted are attributable to the mechanical compression simultaneously employed.

This leads to the consideration of another senseless measure developed in the blind groping for a speedy cure of ulcus cruris. Some powerful intellect conceived the amazing idea that distilled water injected in trifling amounts anywhere under the skin had an undetermined but specific action on the hole in the leg. It was tried out in several hospital cases and made quite a stir—for a while. It did not transpire how the remedy acted. The author did not know himself. It acted; that was all. Eliminating the possibility of self-deception, there must have been contributory elements, because nobody else could duplicate the results. And when we pause to consider how 5 c.c. of distilled water could have any effect in restoring the valves to disorganized veins, or in suspending the action of the law of gravitation, we do not wonder at the coolness of the medical profession with regard to it. Another device that attracted some attention a little while back was packing the chasm with powdered zinc oxide level with the skin and applying a wet boric acid dressing. This had the same defect of ignoring the real etiology, and naturally it fell into disuse. One actual merit it did possess, and that was in acting as a deodorant. This effect was accidental and astonished the clinician quite as much as it delighted the patient. If our only purpose were to remove odor the method just described could not be too highly recommended.

Any method of treatment that leaves out of account the underlying circulatory stagnation may be put aside as worthless. The rational method is to determine, if possible, what is damming the blood back in the veins, remove this, if it is removable, or lend the vessels artificial support from without. The ulcer will take care of itself if the patency of the blood stream is restored. It is not always our good fortune to discover the primal cause of the venous obstruction. We may deduce certain conditions capable of acting in this capacity, but in

the individual case we may not be able to make a demonstration. And even if we are assisted by a fortuitous combination of circumstances in hitting on the cause, we may not be able to remove it, for instance, if it happen to be cirrhosis of the liver. Still it should always be sought for, as occasionally it may be accessible to the hand of the surgeon as in fibroma of the uterus; or to the ministrations of the internist as in chronic constipation. Anything making pressure within the abdomen may be the efficient agent of peripheral congestion. For the matter of that anything making pressure on the vessels anywhere above the site of the lesion may be similarly operative, for example, a truss worn for hernia, or a circular garter below or above the knee. The constriction of the abdomen in form-moulding corsets, causing a ptosis of all the abdominal viscera with the development of intestinal kinks, and stasis; and also the peculiar conditions incident to pregnancy offer a reasonable explanation of the preponderance of ulcus cruris in women. This is strengthened by the tendency of the multiparous to run to fat. If these factors are fortified by a liberal indulgence in alcohol the result is inevitable.

Occupations requiring constant standing predispose to venous sluggishness in the legs. It is noted that motormen are more often afflicted than conductors, and postal clerks than letter carriers, cooks and laundresses than chambermaids. Alcohol congests the portal system and aggravates every other agency, tending to the production of varicose veins. Cardiac disease with failing compensation, and nephritis with edema, will materially assist in the retardation of the ascending circulation. Emphysema circuitously effects the same result.

It may be said that anything lowering the vitality of the individual, and consequently the tonicity of his blood vessels, may be contributary causes. In general terms experience indicates a predominance of vascular atonicity in the intemperate, the obese, the overworked, the multiparous.

Behind the whole question of predisposition lurks that vast indefinite shadow of luetic infection which may be pernicious not only in the direct production of its own peculiar local ulcerations, but in its remote effects upon nutrition, and the intima of arteries—and veins. That explains why competent observers have advocated mixed treatment in all leg ulcers, on the off chance that the frankly varicose might have a possible, long-distance, luetic etiology.

Having accomplished what was feasible in the removal of obstructive factors how shall we handle the local pathological process in the leg? Nothing applied to the ulcer can avail in the least, save in removing foul secretions and deodorizing. The distended veins must be emptied and kept empty. Their valves having broken down they are beyond service unless their lost elasticity can be replaced by an artificial contrivance. Two modes of procedure are available, depending on a slightly different principle. One is that advocated by Lewis A. Sayre nearly thirty years ago, and affording splendid results in patients with a little courage. The swollen limb is immersed in a pail of hot water to the knee. After fifteen or twenty minutes it is removed and a sharp scalpel drawn through the edge and base of the ulcer in a dozen incisions. These involve the whole depth of the inflammatory tissue down to the normal stratum. The bleeding is profuse, because the heat previously applied has temporaliy increased the chronic congestion. This bleeding is allowed to continue for fifteen or twenty minutes and its direct and immediate effect is to deplete the veins that have been overloaded with blood for years. Gravity now aids instead of hampering us. When the flow has slackened, the ulcer is washed with a bland antiseptic like boric acid lotion, dressed with an antiseptic powder like aristol, and basket-strapped, the strapping extending from the ankle to the knee. Over this is applied a sung bandage beginning at the base of the toes and ending at the knee. This dressing is changed in three days. The second dressing is the same as he first. In a month's time under this management, and reasonable attention to the rules of right living, this old grisly stubborn and repellant reproach of the medical profession will be no more. A proper support will prevent a relapse.

The second means of attacking the condition is as I have already hinted based on a slightly different principle, but it is frequently successful in patients with resolution and perseverance. We proceed on the idea of supplying the lifeless swollen veins with an artificial elastic support that contracting and stretching with the movements of the leg will force the blood forward and keep down distention. In this procedure the ulcer itself is practically ignored. The cause is attacked with the assurance that all its consequences will clear up if it is removed. The underlying conception is identical in both methods, viz., to empty the veins. The difference is in the manner of actuating it. In this second procedure a rubber bandage is applied to the limb from the toes to the knee *before getting out of bed.* It is worn all day and taken off *after the patient gets into bed again.* During the night the swollen vessels reduce. The bandage is put on before they have a chance to fill, *i.e.*, before the patient gets in the upright position. By this method the varicose veins are practically removed as they never have an opportunity to sag into a varicose condition. Immediately all the ill effects of varicosity begin to pass away, and in a few weeks the ulceration will heal by the restoration of normal circulation through the part. This is the method proposed by Dr. L. D. Bulkley, and urged on a reluctant and dubious profession for years. It has one drawback. It is apt to set up a dermatitis in some people. But this is never marked, and with a little resolution can be tolerated with the prospect of a greatly counterbalancing advantage.

As remarked, the ulcer is practically ignored. At night a little ichthyol ointment is applied, but this is carefully wiped away in the morning before applying the bandage. A small bit of gauze is put between the ulcer and the bandage, more with the idea of saving the bandage than protecting the ulcer. At night the bandage is rinsed in cold water and looped over a chair to dry.

Both of these methods presuppose a certain amount of nerve on the part of the patient. If deficient in this regard he will not allow the incisions or persist against the discomfort of the rubber bandage. But it is only those with resolution that accomplish anything. The spineless, the self indulgent, the vaccilating, and sceptical neglect, for reasons peculiar to their characters, the relief that is offered by either of the two equally scientific and successful forms of treatment. To quote the vernacular, this "goes" for the doctor as well as the patient.

323 West Fourteenth Street

THE END OF LIFE.

By CRAWFORD RICHMOND GREEN, AB., M.D.,
TROY, N. Y.

It is an interesting fact that the evolution of our society has been such that while we devote much attention to the smallest details concerning our entrance into life, we pay but little attention to those concerned with leaving it. There is, indeed, a great contrast between the careful preparation that is made for the reception of the newborn child and the unpreparedness and neglect which in many cases we find so conspicuous in the hour of death. The former event we anticipate with the keenest eagerness; the latter we would postpone indefinitely, for death, the most unfailing of visitors, is always expected to knock at some other door before arriving at our own.

This contrast between our attitude toward birth and our attitude toward death is but the outward expression of our hopes and our desires. We have come to look upon birth as symbolic of all that is bright and joyful in human life; we regard death as the expression of all that is sorrowful. We are constantly impressed with the fact that death signifies the parting of the ways, the leaving of the world we know for the mysteries of a great beyond, the separation of lifelong ties, for aught we can prove otherwise, forever. There is, indeed every reason why we should prepare for the newly-born in a way that betokens love and watchful care and gentleness; but there is no reason why, because death is unwelcome and undesired, we should be any the less vigilant in the interests of the one who is doomed to die than we were previously; no reason why, because the end of life seems inevitable, we should be seized with panic at its approach and turn our faces to the wall. Our attitudes in these two great episodes of the drama of life are all the more remarkable when we consider that the babe who is conducted to the cradle from its mother's womb is but an insentient organism, wholly unable to react to its environment in any but purely reflex ways; while the adult who faces death, even when appearing to have lost consciousness, is frequently hypersensitive to the finest shades of light and sound. To the newborn child it can make no difference, however much we plan for his reception, whether his entry be in light or in darkness, or whether it be consummated in a palace or a hovel. To the dying adult it *may* make all the difference in the world whether death arrives with the shutters drawn or with the sunlight streaming through the window, or to an accompaniment of soft music or harsh words. It is to this much neglected phase of the end of life that it is our purpose to call attention, and to the obvious duty that it implies.

In considering the state of one who in the natural course of events is soon to die, the first question that naturally arises is whether or not he should be informed that death is impending. There are, perhaps, a few patients who should, if possible, be kept in ignorance of the fact that their illness will probably be fatal. But, in general, it may safely be asserted that one whose condition is considered hopeless should be apprised of the fact as early as possible. Most patients, however, will have reached the conclusion independently some time before the truth is told to them. But, in this connection, the manner in which the patient receives his knowledge is of the utmost importance. We are all familiar with the type of physician, so useful in fiction and on the stage, who, after carefully and seriously examining his patient, looks up and says: "My friend, you've got just three months to live." But the physician who leads his patient gradually and tactfully to the conclusion that death is at hand treats his patient with far greater kindness than the one who bluntly and coldly and at once asserts that "the jig is up."

Nevertheless, in view of our tenacity of life, no one, however hopeless his case may seem to be, should be left without some ray of hope. Drowning men grasp at straws, and sometimes they find them well worth the grasping. One has seen a patient *in extremis* with tuberculosis, emaciated, aphonic, and with horrid bedsores, restored by the wonders of Nature to a life of useful activity after being bedridden continuously for thirteen months; one has seen inoperable cancer entirely disappear where the science of man has played no known part in curing it; one has seen patients who have been given up by their physicians to die of infectious fevers snatched from the very jaws of death and cured by what seemed miracles. Nay, if we think this life of ours worth continuing and hesitate to cross to the world beyond, let us remember the old and trite aphorism: "While there's life, there's hope," and, remembering it, put it to good use. It is a comfort to some types of mind to feel that even after they have reached an apparently hopeless condition, we may after all be mistaken regarding their viability.

Since there is nothing more inevitable than death, we should naturally expect that everyone would keep himself in a degree prepared for that event. Yet those who have arranged their affairs with the end in view constitute a very small minority, and it is astounding how frequently even those who are forewarned through long and progressive illness fail to take advantage of the opportunity afforded them to put their house in order. Occasionally, but only with the greatest rarity, will one encounter such a spirit as Stevenson presents in "Will o' the Mill," who, when death appears, can say like Will: "I have been waiting for you these many years. Give me your hand, and welcome."

In the presence of death, the disability of the patient to manage his affairs makes it incumbent upon others to assume that responsibility. This responsibility, which is one of the most sacred of all responsibilities, falls upon relatives and near friends and, not infrequently, upon the physician. The old type of family physician, however hard his place may be crowded by the modern tendency toward specialism, will always maintain a position which is quite unique as an adviser and a confidant in extramedical affairs. The secrets that have been entrusted to him and the intimate knowledge that he possesses of his patients' affairs, gives him a function in the hour of death that is really far beyond the mere application of medical skill, however important and valuable that may be.

Man is by nature a religious being, and probably we could find no one, however stoutly he might deny it, who has not some faith in God. In the face of death, when no help from man can stem the tide, we turn instinctively toward our Maker. We do this in great companies, as in the case of shipwreck at sea, and we do it singly when death comes to us alone in obscure places. There are probably no rational beings who do not wish and try in some way to make their peace with God before they die. It is, therefore, a sacred and an essential duty of the physician to take every pains in his power to pro-

vide for his patient the solace which religion can afford. The physician, viewing the situation with the purely material consideration of cold, hard, scientific facts, may feel that when his science fails nothing else can be of avail. But when one has seen the resignation and the peace which comes with the ministry of pastor or priest, or the magic effect of hymn or prayer, one's materialism is likely to vanish like a mist.

Whenever possible, there should be opportunity, too, for the consummation of imperative matters of home and business. There is no end to the muddled affairs men leave behind that a tactful physician might have helped to avoid. How frequently we witness the frenzied effort of one who is dying to articulate the words to say something that should have been said long before! How often we see the dying harassed and disturbed by others in their attempt to secure information that they should have secured upon some earlier occasion! Men die without wills because they meant to make them on the morrow; they die with secrets which they would give a fortune to have divulged before it was too late; they die unconfessed and unreconciled in a thousand ways with never an intention of making so sorry an exit from the world. Happy is the man whose physician, coincidently with relieving his bodily distress, will help him get his house in order before he die!

As to the relief of the physical suffering of the dying, there is much to be said. Without some actual experience in the presence of death, it is difficult to imagine how frequently dying persons are permitted to suffer needlessly through the unintentional neglect of their attendants. The writer has stood by the bedside of many who were dying and watched the light flicker from their bodies; but he can recall no instance where something could not have been done for the patient that was left undone. Those who have passed through long and serious illness in which their comfort has been wholly dependent upon what was done for them by others are perhaps the best prepared to shed light upon the subject. An analysis of the sensations which such patients experience will give us many clues to the amelioration of patients in the time of death. A little thought upon this too little thought of subject will indicate how inhuman it is to cease our labor because we know that our charge is about to die, and how terrible it must be to the patient if it reaches his consciousness that all effort in his behalf has come to an end and that the battle is acknowledged to be lost.

What, then, can we do for the patient, if there is no chance to save his life? The gratitude of patients whose condition allows them to express gratitude shows how much little details of attention may mean to their recipient—even details that seem almost too trivial to make them worth considering. One of the chief causes of unnecessary suffering to which those unable to help themselves are often subjected is an uncomfortable position. By frequently changing the patient's position and by closely studying his attitudes and expressions, we can do him a great service by assisting him into the most comfortable positions attainable. We can arrange his clothes so that they will not annoy him. We can see to it that he has plenty of air to breathe, and, if it be available or indicated, we may provide great comfort by the administration of oxygen. By keeping his lips and mouth moist we can do much to allay suffering from thirst. We can keep his mouth clean, and attend to the excretory organs. We can do much to keep him warm with external heat. Above all, we can keep him free from pain. Morphia, the blessed banisher of pain, is at the command of all physicians—there can be no excuse for not invoking the peace its charms induce. In some conditions, such as the terminal stage of tetanus or meningitis, for example, the continuous administration of chloroform or ether to allay the spasms is a highly humane act that should not be neglected until the terrible convulsions have altogether ceased or the end has come. And in many other ways there should suggest themselves to the alert mind and the watchful eye of the *fit* attendant details of comfort that may be adapted to the individual case in hand.

But if our duty requires that we continue to devote ourselves zealously to the matter of physical comfort, it none the less requires that we be equally zealous to protect the peace and comfort of the patient's mind. We can never know just what effect the details of environment have upon the patient who lies in a semiconscious stupor preceding death; but we know what experience teaches in the case of those who are similarly situated in the course of serious illness from which they recover. It is, therefore, easy to reason by analogy from the one to the other. We have all experienced the unpleasant duty of entering a death chamber in which the patient is surrounded by well-meaning but misguided relatives and friends, crowded together in a close, foul-smelling room, all weeping and lamenting. Can one imagine a situation more inhuman or unkind? Or can one imagine a sorrier setting in which to make one's exit from the world?

The hours of sickness and death are the occasions upon which we expect friendship particularly to assert itself. There can be no greater blessing to one who is gravely ill than to look upon the hopeful countenance of some old and faithful friend. But for every friend whose presence is desired there usually appears another whose effect is quite the opposite. The supply of bores and bunglers always seems sufficient to go round. They usually manage, if given the remotest chance, to inquire within earshot of the patient how long the doctor thinks he's going to live, or to remark how sad it is that nothing can be done for him, or to regret that it will be so hard for Mary and the children when he's gone. Conversation of this lugubrious character within the hearing of the patient is common experience. The writer has even heard discussion of the details of the funeral within the hearing of a dying man who was cognizant of every word that was said. Can one imagine more heartless conduct in a society that has the presumption to call itself civilized? Let there be conversation around the patient, if you will—a mournful silence is by no means always to be desired. But let the conversation be directed with a view to its possible effect upon the patient's mind. There will be plenty of time for lamentation and the funeral after we have finished serving the patient during life.

There is, however, something to be said on the side of leaving the patient alone—of giving him a chance, as we say. While it is true that we much more frequently neglect our patients' comfort than otherwise, there are occasions when we add to his discomfort by the very multiplicity of attentions that we shower upon him. An excess of attention may easily be worse than not enough. Too many attendants fussing and bustling about in a noisy man-

ner must be most distressing to one who cannot raise his voice in protest. It is unjust to persist in disturbing the patient when he is already comfortable; it is unkind to keep on administering medicine by the mouth when he can scarcely swallow; it is cruel to keep up the use of hypodermic medication that can be of no avail. It requires a fine discrimination on the part of the attendant to know when the patient should be left alone. In "The Gate of Death," which is the record of the experiences of A. C. Benson upon the two occasions when he was near to death, the author states that his one desire was for solitude, and from this fact he deduces as a generality that one should be allowed to die in privacy. The experiences of others, however, lead us to the conclusion that it cannot be accepted as a standard that one should be left alone to die. Nevertheless, in view of the absolute lack of judgment so often encountered, one can readily imagine that the last prayer of many a patient might be: "O, Lord, deliver me from my tormentors!"

The immediate environment of the patient is, indeed, a matter of serious moment, and one to which we can hardly pay too much attention. It should be the custom, whether the case be one that is fatal or one in which recovery is expected to eventuate, to make the sick room as attractive to the patient as we can possibly make it. If there are in the house any pictures of which the patient is particularly fond, they should be placed where he can see them; if there are any odors which he particularly enjoys, as of flowers or foliage, we should try to provide them; if there is any music for which he particularly cares, we should endeavor to permit his hearing it. A knowledge of the tastes and temperament of our patients, and a careful study of the effects produced by the little details here suggested, would do much to mitigate the passing of life. Our Puritanical friends would doubtless be shocked to enter a house of death to the sound of merry music, or to find that the patient's cot has been carried to the roof so that he may hear the summer breeze stirring through the trees while he looks up at the stars. "Queer people over there," perhaps they'll say. Well, let them; convention and misery have more than once gone hand in hand. It is only convention, unsupported by philosophy, humanity, or common sense, that requires that the last conscious impression of this world shall be one of sorrow and suffering. There are two ways of looking at it, and, as in so many things, we allow the sadder to prevail. It is as though upon a college commencement day the atmosphere were permeated with regrets for the happy days just ending, instead of joyful confidence in a wider horizon of life that lies beyond.

We are often told regarding a patient that his case is hopeless and the doctor has given him up, or the doctor has stopped coming because he can do no more. One must submit that medical ideals and traditions cannot improve so long as there are physicians who give their patients up or physicians who can do no more. It must be an awful experience to the dying to sense from the conduct of the physician that he has given up the fight. No fight with death is ever lost until the final curtain falls; and if the patient has reposed his confidence in the physician, if he has given his life into his keeping, his confidence should be honored as a sacred trust to be guarded steadfastly to the end.

Medicolegal Notes.

X-Ray Photographs—Necessity for Verification.—In an action against a physician for malpractice in connection with the treatment of a broken arm two *x*-ray photographs were introduced for the plaintiff, one of which a medical witness testified he took before the operation was performed, the other afterwards. The defendant contended that there was no proof that either of these photographs correctly represented the condition of the arm at the time it was taken, and that they were therefore inadmissible as evidence. The use of photographs as testimony to the objects represented rests fundamentally on the theory that they are the pictorial communications of a qualified witness, who uses this method of communication instead of, or in addition to, some other method. In order to be admissible as evidence, such photographs must have the support of a competent person's oath. This rule applies to *x*-ray photographs, and where the witness who made the photograph, and who is the only person who can show that it does represent the fact as he saw it, fails to make an *x*-ray photograph admissible by testifying to its accuracy, it is not admissible and should be rejected. Here the witness merely stated that he took the photographs. He did not state that they correctly represented what he had seen, or how they were taken, or that he had ever taken an *x*-ray photograph before, or knew anything about how they ought to be taken. He gave no assurance as to the character or accuracy of his *x*-ray machine, or its condition or working order. While it might not have been necessary to establish all of these facts in order to make the photographs admissible under the rule stated, the testimony given was held to be insufficient to establish the accuracy of the photographs, which should therefore have been excluded.—Ligon vs. Allen, Kentucky Court of Appeals, 162 S. W., 536.

Liability of Operating Surgeon for Negligence of Hospital Nurses, etc.—In an action against an operating surgeon for damages caused by the hospital attendants in negligently leaving gauze in the wound after dressing it, causing pulmonary tuberculosis, it was held that an operating surgeon who operated at a number of different hospitals is not liable for the negligence of hospital surgeons, nurses, or internes in the after dressing of such wounds, if such operating surgeon is without knowledge of, or not privy to, such negligence.

It was held that a question to a medical witness whether it was the invariable custom among competent surgeons to personally apply all dressing following the operation where the patients are treated in hospitals was proper. The defendant was properly asked whether the dressing of wounds after operations in such cases was difficult, as bearing on his negligence in leaving the dressing of the wounds to the hospital authorities. As the plaintiffs claimed that the tuberculosis was the result of the gauze and rubberized silk being left in the wound, it was proper to ask a medical witness to state how, in his judgment, the sinus left from this wound became infected with tuberculosis, and what connection, if any, the tuberculosis condition of the sinus had with the operation or subsequent treatment of the case by the defendant. Evidence as to how long it usually takes such a wound to heal was held to be admissible. And evidence as to the custom in general hospitals in the caring for and treatment of patients after operation was admissible.—Hunner vs. Stevenson, Maryland Court of Appeals, 89 Atl., 418.

Contagious Diseases—Proof of Cause.—A policeman was dismissed from the police force of the city of New York on a finding of guilty upon charges of conduct unbecoming an officer. The specification was that he had contracted syphilis at some time in the past, and was then affected with the disease. In proceedings to review the determination it was held that a court may take judicial notice that syphilis may be contracted by a person entirely innocent of sexual commerce with one tainted therewith. No attempt was made to show that the policeman contracted the disease directly as the result of immoral practices or of loose conduct. On the other hand, he was not allowed to testify that such was not the cause of his affliction, if the existence of the ailment was established. For aught that appeared, the punishment of dismissal was inflicted for innocent misfortune, not conscious misdoing. The policeman was reinstated.—People vs. Waldo, New York Appellate Division, 143 N. Y. Supp., 818.

CANCER STATISTICS.

"FIGURES," they say, "cannot lie"; yet of some notorious truth strangler one may hear remarked that "he lies like a bunch of statistics." One needs to keep these contradictory sayings in mind in taking note of the present controversy regarding the alleged increase in cancer. Writers of authority and statisticians of the first rank are notoriously at odds over this question, and each side supports its own contention with a mass of apparently irrefragable statistics. It may be conceded that figures, as such, cannot lie but they may be derived from unsound bases, and can be manipulated by an obstinately prejudiced, even though conscientious, statistician, in a way to mislead the most wary.

The general impression no doubt is that cancer is alarmingly on the increase and this impression is strengthened by many writers in both the medical and the lay press who seem to have the figures on their side. The value of these figures is, however, hotly disputed by men of equal repute as conscientious observers, who doubt the fact of an increase and believe that the spreading abroad of such alarming reports will react with cruel force upon the fears of many timid folk. They say that the apparent increase is due to the fact that the registration area, that is, the extent of territory in which approximately accurate mortality statistics are published, is constantly widening and that consequently the number of deaths reported as from cancer is growing larger each year. But while this would show an absolute increase it ought not to alter the relative mortality. There is, however, seemingly an increasing percentage of deaths from cancer as well as an absolute increase in their number. To this the reply is made that these mortality statistics are unreliable, especially in this country where the registration area is yet restricted and where physicians, even in the registration cities, are not trained to statistical accuracy. Both sides use the argument of an increasing exactness of diagnosis; one side contends that many tumors are now diagnosed as malignant which in former times would not have been so recognized, hence the increase in the cancer rate is apparent only; the other side says that in the old days the profession in general, as the laity even yet, was prone to pronounce all tumors, especially if pain-producing, cancerous, hence the more discriminating diagnosis of the present tends to minimize rather than exaggerate the fact of an increase in cancer.

As to the diagnosis of cancer *intra vitam*, it may be doubted whether there was any real improvement in that during the fifty years preceding the present decade, and even to-day (outside of the laboratory, whose findings are not yet absolutely infallible) the early diagnosis of malignant disease is largely a matter of conjecture. Early operation, which is now more common, might give opportunity for a more positive diagnosis, but if it really is as curative as present-day surgeons think, and not merely a postponer of the inevitable, its result should be to diminish the mortality rate from cancer. On the other hand, operation for so-called "precancerous" lesions ought to reduce materially the incidence of cancer, if they are right who preach that malignant disease is always engrafted on some previously innocent lesion.

Weighing all the evidence presented by one side and the other in this controversy, it seems permissible to believe that there is a slight increase in the prevalence of cancer at the present time, whether because the modern diet or mode of living is conducive to some fault of metabolism which lies at the foundation of malignancy or because the improved hygiene of to-day permits more people to live to the cancerous age. But the figures which seem to show this increase are not beyond disproof on skilful analysis, and it is doubtful whether, for some years to come, any statistics will be available by means of which this question can be definitely settled. The disputants would do well to wipe off the slate and start afresh, agreeing to use only those statistics obtainable from places which have been included in a registration area for a certain time, say ten years, during which physicians on whose returns the figures are based will have been educated up to an appreciation of the value and the morality of accuracy in making out certificates of death, not regarding the prejudices of the relatives who seem to regard the misfortune of cancer as also a reproach, and fortifying the diagnosis whenever possible by a postmortem examination or at least the microscopical examination of a fragment of the suspected growth. Then there might be some reason for pronouncing upon the near accuracy of the figures, and the deductions made from them could be more readily accepted as approximately correct.

PARALLELISM BETWEEN HYSTERIA AND DEMENTIA PRECOX.

THE relationship between hysteria and dementia precox is a subject which has been receiving considerable attention of late years. The progress in this direction has been quite rapid and many interesting parallelisms have been noted. We may enumerate here some of the most noteworthy contributions to the elucidation of this very fascinating, interesting, and important problem.

In his excellent treatise entitled the "Psychology of Dementia Precox," (Nervous and Mental Disease Monograph Series, No. 3) Jung shows in an admirable manner how nearly related are these two

mysterious and mystifying conditions. The emotional apathy of the dementia precox patient may be compared to the indifferent, "I don't care" attitude of the hysteric. Just as in hysteria indifference may suddenly give way to an emotional storm, be it a crying spell or the like, so also in dementia precox the apathy may suddenly be displaced by tumultuous, explosive attacks, impulsive, emotional outbursts. It is, however, to be noted that the blocking of the affect is greater in dementia precox than in hysteria. In both conditions we observe the occurrence of obsessive ideas, anxiety states, disturbed affective states, these being of an origin apparently unknown to the patient. In both conditions we find delirious episodes, irrelevant replies to questions, stupor, vasomotor disorders, and peculiar disturbances of consciousness. External mannerisms, affectations of speech, voice, and gait, originality, and stupidity may be present in either disease. Carelessness of others, selfishness, narrow-mindedness, prejudice, inaccessibility to persuasion, and decided egocentricity come to the surface in both diseases. In the precox patient as well as in the hysteric we come upon narrowing of the field of consciousness, difficulty in fixing the attention, and certain vague preoccupations. We find also, as Jelliffe notes, that the obsessive ideas of the hysteric can be compared to the delusions of the precox patient. Stereotypies and sensorimotor phenomena may appear in both conditions.

Evenson, in his work on Dementia Precox, calls our attention to the fact that such prominent symptoms in precox as negativism, stereotypy, and peculiar attitudes are very similar to the reactions of normal individuals occupied by one thought. He further argues that in preoccupied individuals and in the catatonic the fundamental disorder may be found in the narrowing of the field of consciousness about a central content. Evenson also mentions the relationship between hypnosis and catatonic stupor. This is quite in line with what we have known for some time about the relationship of hysteria to hypnosis. So close has this relationship been found to be by certain observers that the dictum has been formulated that to be hypnotizable meant that one was hysterical. In other words they were viewed as being quite alike, except that one was an artificially produced condition while the other was not. Jung has stated that the psychological mechanisms of dreams and hysteria are very closely related to those of dementia precox. In dementia precox we meet a greater degree of mental dilapidation and dissociation than we do in hysteria. This is due to the fact that the origin is deeper, probably complicated by organic factors of some unknown nature. Coriat well says (*American Journal of Insanity*, IXX, 3, 187): "When the underlying complexes control the entire mental life we have dementia precox, when they merely lessen the amount of energy at the disposal of the patient, we have hysteria."

That hysteria and dementia precox are both conditions arising from mental dissociation or splitting of the mind or personality is generally conceded by all students of psychopathology. Bleuler has permitted himself to go to the extent of calling dementia precox "schizophrenia," the synonym for splitting of the psyche or mentality, and has included under this heading all conditions which are characterized by a splitting of the personality or consciousness, and which, as a consequence, present evidences of contraction of the field of consciousness. This conception, although helpful in permitting us to understand better certain similarities in many heterogeneous conditions, is, however, not to be encouraged, since it would do away with our efforts toward more scientific and precise classification. Conditions of widely different origin or nature may show a certain number of similarities. Relationship is no proof of identity. Bleuler and Jung have endeavored to analyze the somatic and psychic symptoms of dementia precox patients according to Freud's ideas as originally applied to hysteria. They have, however, assumed a too exclusively psychosexual standpoint.

THE ISOLATION OF TYPHOID AND PARATYPHOID BACILLI.

THE comparatively close biological relationship among the members of the colon-typhoid group has always presented a certain amount of difficulty in an attempt to isolate one of these organisms in the presence of one or more of the others. For this purpose there have been devised a number of special media, many of which fulfil their purpose admirably. In the examination of the stools, however, special difficulties obtain. The predominant organism is the *B. coli* and its growth is so luxuriant that in order to be able to detect colonies of the typhoid and paratyphoid bacillus in plates it is necessary to inoculate them with a rather high dilution of the fecal mass. Under these circumstances it is probable that at times a search of the stool for typhoid results negatively because, in the specimen taken, the organism was present in too small numbers. Some method of "enrichment" of the stool is therefore desirable which shall either increase the typhoid bacilli without favoring the growth of the coli, or which shall hinder the development of the colon bacillus without injuring the *B. typhosus*. The use of bile media is of some help to this end but has not always given altogether satisfactory results.

Bierast believes (*Centralbl. f. Bakt.*, 1914, lxxiv, 348) that he has found an ideal agent in petroleum ether. His method is to rub up the feces with nutrient broth until a very thin emulsion is obtained. This is put into a tube and petroleum ether (B.P. 40) added. The tube is corked and shaken for five minutes, allowed to stand for fifteen minutes, and again thoroughly shaken. It is then allowed to stand for about fifteen hours at room temperature in a dark place. Plates were stroked with material from the middle layer found after standing thus. In all of his experiments he found that the great majority of the colon bacilli were killed or at least did not develop, while the typhoid and paratyphoid bacilli were apparently unaffected. The bacilli of the dysentery and the enteritidis group were not as resistant as the typhoid to this

agent but were apparently only slightly interfered with. He found that some strains of the colon bacillus were more resistant than others but that in every instance they were markedly affected. He was unable to ascertain in what manner the petroleum ether acted upon the coli, but does state that their form and staining reactions are apparently unchanged. If this method comes up to the author's expectations it ought greatly to increase the facility of the discovery of the typhoid bacillus in the stools. This is greatly to be desired for the present methods are tedious and uncertain and it is becoming almost a routine in some of our hospitals to examine the stools of typhoid convalescents before discharge to determine whether they are carriers.

Femina Militans.

The British suffragette is naturally receiving attention at the hands of medical jurists in other countries, and last June she was discussed before the Medico-Legal Society of Berlin (*Berliner klinische Wochenschrift, June* 20.) The phenomenon of militantism, said Marx, is an inversion of the seemingly natural passivity of woman, and is due to a certain immaturity of the brain, which is exhibited in the violent "short cut" toward a desired object. Violence has been termed the weapon of the weak. We are reminded in this connection of the young men of Greece, of whom the philosophers said that young men "use the harshest measures first." Marx absolves the women from hysteria. In passing he mentions other types of femina militans, in which the natural passivity of the sex is inverted, and women have revolted against what they believed to be a withholding of their rights, but in the modern type it is the ballot alone which is sought. In fixing punishment, each militant, Marx says, should be dealt with as an individual, and no wholesale penalties be carried out. Leppmann would not class the suffragettes indiscriminately as criminals. He would look into the components of imbecility and psychic infantilism. Strassmann classed the suffragette movement as a "crowd psychosis." Mass believed that no sane woman could die by hunger strike. Marx in closing said that the movement was a pathological development of neofeminism. The question of feminine militancy is now, however, for the time being at least, a thing of the past, overshadowed by the militancy of hordes of the ruder sex. The woman has resumed her rôle of ministering angel and is devoting her energies to relieving as far as she may the suffering caused by the combatants in the larger war.

Atypical Gout.

In theory the English medical men should be better suited to deal with this subject by reason of the predominance of true gout in the British Isles, and, as a matter of fact, they have published much on the gouty diathesis, uric acid, nephrolithiasis, and the like. On second thoughts, however, the infrequency of typical gout in other culture countries suggests that there may be an excess of unrecognized atypical gout in such localities in which genuine gout is infrequent. A paper read by Goldscheider on this subject before the Berlin Medical Society last June (Medical Record, August 15) was followed by a very full discussion (*Berliner klinische Wochenschrift, July* 20.) Umber stated that tophi could form without the presence of gout of any sort. He had seen them in a woman with destructive polyarthritis, who showed no disturbances in the purin metabolism. The tophi contained not a trace of urates. Creaking of the joints, so often imputed to incipient gout, might have a purely static origin as seen in the feet and knees of heavy men. Of course, one could waive the question of abnormal purin metabolism, and seek to include arthritis deprimans and destruens, Heberdensnodes, etc., under irregular gout, but this is quite unjustifiable, Heberden asserted positively that his nodes do not occur in the gouty, although pathologically they could be classed under tophi. Von Hansemann has made autopsies on subjects dead of definite illnesses who had in life exhibited extreme creaking of the knees, elbows, and other joints, and found absolutely nothing abnormal in the affected articulation. Brugsch thought the main question was whether or not uric acid played any rôle in some of these affections of joints and bursæ, tophi, etc., in which a gouty diathesis could apparently be excluded.

News of the Week.

Health of Canal Zone.—On April 1, 1914, the Department of Health of the Panama Canal was organized on a permanent basis, the name being changed from "sanitary department," and the "chief sanitary officer" becoming the "chief medical officer." This position is now held by Lieut.-Col. Charles F. Mason, Medical Corps, U.S.A.; formerly superintendent of the Ancon Hospital. Several other changes in the personnel were also made. During the month of May the health of the employees continued good. No cases of yellow fever, smallpox, or plague originated on or were brought to the Isthmus during the month. The total number of admissions to hospitals and quarters was 1,633, or a rate of 407.92 per thousand per annum, as compared with 350.59 for the preceding month, and 468.59 for the corresponding month of last year. The total number of deaths from all causes among employees was 39, of which 23 were due to disease, giving an average annual death rate of 9.74 per thousand. Lobar pneumonia caused 7 deaths, and tuberculosis, 6. The work of sanitation, including street cleaning, rat catching, destruction of breeding places for flies and mosquitos, control of infectious diseases, vaccination, etc., is being actively carried on.

Death Rate Lowered.—During the week ending August 1, the deaths in New York City numbered 72 less than those during the corresponding week of last year, the most noteworthy decrease being in the deaths due to diarrheal diseases among infants.

Child Labor Decreasing.—A recent report on occupations from the Bureau of the Census shows that between 1900 and 1910 there was a decrease of 129,236 in the number of children between ten and fifteen engaged in non-agricultural pursuits. Of this number 77,666 were boys, and 51,570 girls.

Public Health Director.—The Department of Health of the City of New York has recently created a new position under the title of Director of Public Health Education, the incumbent of which will be appointed by the Municipal Civil Service Commission. The duties of the director will be to organize and administer a bureau dealing with all

phases of public health education; to prepare and edit popular and scientific bulletins dealing with public health matters, including the regular health publications of the Department of Health; to organize exhibits and courses of lectures dealing with various features of public health work; to cooperate with existing teaching institutions in organizing a school of sanitary science; to secure the dissemination of public health information through moving picture theaters, leaflets, conferences, press bulletins, etc.

Personals.—Dr. Benjamin Jablons of New York has received from King Peter I of Servia, the Order of St. Sava.

New Hospital Site.—The Williamsburg Hospital, Brooklyn, which has for over fifty years been located on Bedford avenue, has recently purchased as a site for a new building a plot 100 by 123.6, at Driggs avenue and South Ninth street. On this a modern hospital will be erected at a cost of about $125,000.

Information on Typhoid Fever.—The New York City Department of Health announces that it has issued a new folder which is intended to instruct "the man in the street" on how to avoid contracting typhoid fever. This information is given in condensed form and is printed in four languages —English, German, Italian, and Yiddish. Five hundred thousand copies have been prepared and will be distributed through nurses, insurance companies, branches of the New York Public Library, and charitable organizations, without delay, so that the information may be utilized to forestall the usual autumnal increase in typhoid fever. It is expected that through the co-operation of these agencies in the distribution of these folders, substantial progress in the campaign for the prevention of typhoid fever will be made.

Gifts to Charities.—The Post-Graduate Hospital, New York, receives under the will of the late Miss Cora V. C. Catlin, a bequest of $5,000 for the endowment of a bed in the children's ward to be known as the N. W. S. C. bed.

Civil Service Examination.—The Philadelphia Civil Service Commission will hold, on September 22, a competitive examination of the position of chief resident physician in the Philadelphia General Hospital, Department of Public Health and Charities, at a salary of $4,000 a year. Applicants must be citizens of the United States but not necessarily residents of Philadelphia. The Chief Resident Physician of the Philadelphia General Hospital is the medical and executive head of the hospital, which contains 2,000 beds. He should be between twenty-eight and fifty years of age, and must be a graduate of a reputable medical school, who has had some experience in a hospital. Application for permission to take the examination may be made in person or by letter to the Civil Service Commission, Room No. 875, City Hall, Philadelphia. No applications will be received after September 19, 1914.

Iowa Licenses.—Certificates to practise medicine in Iowa were issued by the State Board of Health on July 25 to sixty-nine physicians who had successfully passed the examinations held on June 9.

Hospital Burned.—The Pasadena Sanatorium in South Pasadena, Cal., was destroyed by fire on July 25. The sixty patients in the institution were removed without mishap. It is estimated that the loss was about $30,000.

Tetanus Serum Called For.—One of the echoes of the European war here was the request received by the New York City Health Department from the Vienna Serum Institute, for fifty liters of tetanus antitoxin. The Health Department will have the serum prepared and forward it through the Austrian Consul.

Red Cross Active.—The International War Relief Board of the American Red Cross has decided to charter a big vessel for the purpose of sending hospital supplies to the foreign Red Cross societies involved in the war. The ship will carry hospital units, consisting of three doctors and twelve nurses each, and these will be assigned to work in the different countries as the need arises. The matter of securing the vessel and of obtaining supplies and organizing the units is in the hands of members of the Medical Corps of the United States Army and Navy.

The American Hospital in Paris and its staff of twelve surgeons have offered their services to the French Government and have arranged for a field hospital in the gardens at Neuilly. An ambulance service has been installed at the Lycée Pasteur near the hospital, and the equipment is ready to go to the front at any time.

Drug Trade Suffers.—The trade in drugs and chemicals is probably the one which has and will suffer most severely because of the interruption of our dealings with foreign countries because of the war. In the last few days the prices of all drugs, chemicals, and essential oils have advanced from 20 to 100 per cent. On August 8, morphine was quoted at an advance of 20 cents an ounce, and opium at an advance of $2 an ounce. Quinine, for which Hamburg is the center, had advanced to 35 cents an ounce, and cod liver oil from Norway was selling at $28 a barrel, an advance of $11. The United States as the largest drug-consuming though the smallest drug-producing country of the world, will naturally suffer greatly from this interruption of trade. Most of the synthetic antineuralgies and hypnotis, as well as salvarsan, are German products.

Obituary Notes.—Dr. HERMAN BERBERICH of Philadelphia, a graduate of the Philadelphia College of Pharmacy in 1898, and of the Jefferson Medical College, Philadelphia, in 1901, died by drowning at Wildwood, N. J., on July 26, aged 37 years.

Dr. JAMES FORSTER ALLEYNE ADAMS, of Pittsfield, Mass., a graduate of the Harvard University Medical School, Boston, in 1866, a medical cadet in Farragut's fleet during the Civil War, and a member of the Massachusetts and Berkshire District Medical Societies, died at his home on July 27, aged 60 years.

Dr. GEORGE E. KING, of Wedonia, Ky., a graduate of the Kentucky School of Medicine, Louisville, in 1898, died on July 20, from tuberculosis, after a long illness, aged 40 years.

Dr. HAGOP H. THOUMAIAN, of Saint Anne, Ill., a graduate of the Northwestern University Medical School, Chicago, in 1896, died in the Presbyterian Hospital, Chicago, on July 18, aged 47 years.

Dr. WILLIAM HENRY CARPENTER, of Brookline, Mass., a graduate of the Dartmouth Medical School, Hanover, N. H., in 1876, died at his home, after a long illness, on July 23, aged 77 years.

Dr. CHARLES EDWARD BOOTH of Minneapolis, Minn., a graduate of the Rush Medical College, Chicago, in 1872, died at the Asbury Hospital, Minneapolis, on July 25, aged 74 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

THE CONGRESS SEASON—CLINICAL SURGEONS OF NORTH AMERICA—PUBLIC HEALTH.

London, July 31, 1914.

ANNUAL meetings, conferences, congresses, are just now in full tide. The British Medical is the most numerous association, and its members are spread over the whole country. Many attend its annual meetings, where the general condition of the profession and its so-called politics excite as much interest as medical problems. You will probably receive some account of its doings from your reporters. Another congress attracting attention is that of the Surgeons of North America, which is meeting in London this year. A good number are here for it, and they are interested, I find, in our hospitals and other institutions, and, of course, especially in the surgical clinics. Dr. John B. Murphy, of Chicago, gave a sort of presidential address at their first meeting, in which he described his work in arthroplasty, and mentioned some striking cases. But you will be fully informed about his methods and work. Here it is known to not a few. The Congress was welcomed by Sir R. Godlee and your ambassador here. Lectures have been given during the week at the Royal College of Surgeons on specimens in the Hunterian Museum by the president (Sir Rickman Godlee), Professor Keith, and Messrs. Shattock, Colyer, and Cheatle, so that the visitors have been able to see the most of these treasures in the shortest time. A reception was also given at the college on Wednesday afternoon. Different hospitals, general and special, were visited, and I am informed the managements gave to the visitors a favorable impression of British surgery.

Another congress which met somewhat earlier in Edinburgh was that on Public Health. At this tuberculosis intruded into several sections: In State Medicine, Dr. Leslie Mackenzie, member of the Scottish Local Government Board, presided, and in his address said that the problem of the next five years would be to dissociate tuberculous patients from unsuitable homes—a supplementary problem being how to fit the homes to the patients' needs. The dispensary here, he thought, had a function, but the first necessity was not advice nor supervision at home, but hospital beds and open-air treatment. He hoped the Executive Research Committee, with its income of £60,000 per annum, would help scientific men to bring their best methods to the aid of administrative bodies. In the section on sanitary administration, the medical officer for Edinburgh, Dr. Williamson, declared that experience showed that only a small proportion of patients on leaving a sanatorium could be considered free from infection, and a still smaller proportion as cured. Most of these patients were removed from poor districts, and after a time were permitted to go back to the same conditions under which they had previously lived—generally to the selfsame homes. There they would still be living foci of the disease, tending to spread it under the very conditions which had proved to foster it. The key to the situation was clearly the housing question.

In the section set apart for tuberculosis, Sir R. W. Philip presided and gave a summary of the advances made in the treatment of phthisis.

In the section on child welfare, Professor Beattie read a paper on the electric heating of milk, which he found destroyed the germs without in any way deteriorating the quality of the milk.

The Naval, Military, and Colonial Section's meeting was practically abandoned on account of an unusual circumstance. A number of papers were anticipated, but the authors were called away to the mobilization of the fleet at Portsmouth. Fleet-Surgeon Bassett Smith, professor of clinical pathology and tropical medicine in the Royal Naval College, Greenwich, pointed out in his address that during the last ten years valuable work had been done to improve the health of the navy, as well as to make the sailors' life a happier, healthier, and altogether better one.

Sir Christopher Nixon, late president of the Royal College of Physicians, Ireland, died in Dublin on the 19th inst., in his 64th year, after a fortnight's illness. He had been chancellor of the old Royal University of Ireland, and when the National University took its place became vice-chancellor of the new institution. This year he was made a member of his Majesty's Privy Council in Ireland. He was a member of the General Medical Council since 1897. His "Handbook of Hospital Practice and Physical Diagnosis" had considerable success. He also communicated papers on the circulation and nervous systems.

OUR BERLIN LETTER.

(From Our Regular Correspondent.)

GERMAN CONGRESS OF SURGERY—POSTOPERATIVE ABDOMINAL HERNIA—PLASTIC SURGERY OF THE NOSE—RADIATION TREATMENT OF TUMORS—THYROID TRANSPLANTATION—THYMUS EXTIRPATION IN TREATMENT OF GOITER—TUMORS OF THE BLADDER—CONGRESS OF INTERNAL MEDICINE—NATURE AND TREATMENT OF INSOMNIA—TREATMENT OF INTERNAL DISEASES WITH ANIMAL CHARCOAL—RADIUM TREATMENT OF INTERNAL TUMORS—BEHRING'S METHOD OF DIPHTHERIA PROPHYLAXIS.

Berlin, July 15, 1914.

THE Forty-third German Congress of Surgery was recently held. One of the subjects that came up for discussion was the cause and treatment of postoperative abdominal hernia. Sprengel, of Brunswick, introduced the symposium with a paper in which he recommended the use as much as possible of the intermuscular incision. In difficult cases he thought the best results were obtained with the use of a mattress suture of catgut with superimposed stitches of fine linen thread. The use of packing is not without danger. Secondary suture in cases in which drainage has been employed is not justified. The speaker recommended strongly the transplantation of free fascia, and instead of plastic surgery he uses foreign material and inert muscles.

The plastic surgery of the nose was the subject of a paper by König, of Marburg. His method of employing the ear muscles has been applied by him and by others in 47 cases, 45 of which healed nicely. He described a new procedure by which he was able to supply the necessary supports for the bridge, septum, and wings of the nose from the sternum and two ribs. The results in two patients were very good.

The radiation treatment of tumors came up for extended discussion. Final judgment as to the efficacy of this method of treatment will not be possible for a number of years. The radiation treat-

ment employed to the exclusion of other methods is to be considered only in the case of inoperable tumors. In all operative cases there should be employed first the knife and then the rays. There is still considerable room for improvement in the technique of radiation, for this may destroy healthy as well as diseased tissue.

The permanent results of thyroid transplantation in human beings were discussed by Kocher, of Bern, who has treated 93 cases by means of this method, and without results in only 18. Transplantation was made into the bone marrow, the peritoneum, the spleen, and other organs. The best results were obtained in the case of transplantation into the spleen. The pieces of thyroid were best taken from the gland removed from patients with exophthalmic goiter, since in these instances the activity of the thyroid is most marked.

Very favorable results were reported by von Haberer, of Innsbrück, in the removal of the thymus gland in the treatment of goiter and of exophthalmic goiter. All of his sixteen cases made a good recovery. Particularly in exophthalmic goiter were the results good. The speaker maintained that in cases of enlargement of the thymus the combined operation on the thymus and on the thyroid is the operation of choice.

Tumors of the bladder were the subject of a paper by Hildebrand, of Berlin, who believed that the operative treatment gives bad results. Permanent cures are rarely obtained by this method. This is to be attributed partly to the fact that the lymph nodes are widely scattered and their removal requires opening the peritoneal cavity at many points. As regards papillomata, in all cases intravesical extirpation would be indicated if it were not for the fact that fifty per cent. of these tumors contain carcinomatous elements. For this reason incision into the bladder is to be recommended even though the mortality is eight or nine per cent. The treatment of bladder tumors by means of the high frequency current was favored by Joseph, of Berlin.

At the Thirty-first Congress of Internal Medicine the nature and treatment of insomnia came up for discussion. The first speaker, Gaupp, of Tübingen, advanced a theory concerning the origin of sleeplessness. Whereas formerly the waste products of the muscles were regarded as the factors in the production of fatigue and sleep, there is a tendency nowadays to regard the metabolic products of the central nervous system as the most important causative factors. In healthy individuals sleep deepens rapidly during the first hour, attains its greatest intensity before the end of the second hour, and then gradually lightens. For this reason one can conceive of the great recuperative value of a short and deep sleep, and one can understand how Frederick the Great, Napoleon, and Virchow could get along with four or five hours' sleep. The remedies for insomnia should be those that put the patient to sleep and that exercise their narcotic power only for a short time. The second paper on this subject was read by Goldscheider, of Berlin, who stated among other things that the most common fact in the disturbance of sleep is that external and internal causes counteract the diminution of nerve irritability, which diminution lies at the basis of sleep. The methods in the general treatment of insomnia are: (1) The removal of the factors that disturb sleep. (2) Physiological treatment. (3) Strengthening of the disturbed self-regulating mechanism. This method demands alternating periods of nervous activity and of rest. By this means there is diminished the state of excitability which is present at the onset of sleep. (4) Physical therapy. (5) Dietetic treatment. (6) Pharmacological treatment. The next speaker, Faust, of Würzburg, discussed the various narcotics from the viewpoints of their pharmacological characteristics, their indications, and their contraindications.

The treatment of internal diseases with animal charcoal was the subject of a most important paper by Wiechowski and Adler, of Prague. The former showed that colloidal bodies if mixed with animal charcoal are not absorbed and that the absorption of crystalloid bodies mixed with animal charcoal is greatly delayed. Adler has experimented with animal charcoal in the treatment of gastric and intestinal diseases and of poisonings in animals. In particular, cases of intestinal catarrh, and of meat and sausage poisoning, are favorably influenced. All severe cases of poisoning by phosphorus, corrosive sublimate, lysol, arsenic, and potassium chlorate, treated by means of animal charcoal, recovered.

The radium treatment of tumors of internal organs was also one of the subjects that came up for discussion before this congress. Good results were reported in the case of cancers accessible from the outside. In cancer of the stomach the operative treatment is preferable. In deep-seated tumors the use of *x*-rays is to be elected, but superficial growths are best treated with radium and mesothorium. Favorable results were also reported in cases of tumors of the lymphatic glands and in cases of leucemia. One of the causes of failure is the use of insufficient doses, for in this manner only stimulating effects are produced and the tumors grow more rapidly.

Diphtheria prophylaxis was the subject of a paper presented by von Behring, who aroused considerable interest with the description of his method of protective inoculation in which diphtheria toxin is partly neutralized by means of antitoxin. The investigations on this subject have already been carried out on about 5000 individuals. In 80 per cent. of the cases antibodies were produced. In most instances one inoculation sufficed.

FIFTH ANNUAL SESSION OF THE CLINICAL CONGRESS OF SURGEONS OF NORTH AMERICA.

(From Our Special Correspondent.)

LONDON, July 30, 1914.

A NEW departure has been made by those responsible for the management of the Clinical Congress of Surgeons of North America by the holding of its fifth annual session in London.

Undoubtedly, the surgeons of London and of England welcomed this move, not only because it gave them the opportunity to meet the surgeons of North America but because it inaugurated in England the system of making the paramount feature of such congresses clinical demonstrations, a plan which is now generally followed in the United States and Canada. Moreover, it afforded the visitors the chance of witnessing British operative methods, the technique and the somewhat different modes of conducting clinics which distinguish the British surgeon from his American confrère. Of course, no better center in the world from the surgical standpoint could have been chosen than London. In wealth of hospital material it is equaled by no

city with the possible exception of New York itself. In hospital facilities, too, London is conspicuous. It contains hospitals of every description. Some old, some middle aged, a few quite modern, while the majority are a composite of the old and new. To use a slang phrase, the London hospitals did themselves proud for the visitors. Clinical demonstrations took place in no fewer than twenty general and special hospitals, and these were so thoroughly appreciated that the capacity of most of the operating theaters was not equal to the demand for seats or standing room and, in many instances, would-be spectators were turned away. To avoid overcrowding the excellent scheme was put into force of issuing special tickets for each clinic and demonstration up to the capacity of the room in which the clinic or demonstration was given.

On Monday evening, July 27, Dr. Franklin H. Martin, secretary general, gave a presidential dinner in the Hotel Cecil. At the dinner among those present were Sir Rickman J. Godlee, president of the Royal College of Surgeons, and chairman of the London Committee of Arrangements; Mr. W. H. Page, the American Ambassador; Sir Watson Cheyne, the president-elect of the Royal College of Surgeons; Sir Francis Champneys, the president of the Royal Society of Medicine; Mr. F. C. Dwyer, president of the Royal College of Surgeons of Ireland; Sir Thomas Barlow, president of the Royal College of Medicine; Dr. John B. Murphy, president of the Clinical Congress; Dr. W. L. Rodman, president of the American Medical Association; Dr. Thomas J. Watkins, president of the American Gynecological Society; Sir Arbuthnot Lane, Sir St. Clair Thomson, Dr. C. H. Mayo, Mr. Herbert Paterson, Mr. H. S. Pendlebury, Mr. W. H. Jessop and Dr. A. B. Kanavel.

After the dinner the serious business of the Congress began in the large banqueting hall of the Hotel Cecil. Sir Rickman J. Godlee in an address of welcome expressed his regret that the annual meeting of the British Medical Association should be taking place at the same time as that of the Congress. Because of this several well-known London surgeons were unable to take part in the welcome that was being extended to the surgeons of America.

Dr. J. B. Murphy, president of the Congress, in the course of his remarks said that the work to be conducted during the week was a colossal undertaking. Such a task had never been undertaken by the Congress away from home. American surgeons would return with a high impression of London surgery. Highly as they had esteemed it before, they would esteem it higher still. They would return to their own country with an admiration and affection for the profession and people of Great Britain and with a feeling that science was a brotherhood that extended around the globe.

The American Ambassador said one of the most distinguished teachers of surgery in England had remarked to him recently that he said frequently to his students that no man had a right to consider himself well started in the great profession of surgery unless he had been to the United States to see the skill that the American surgeons possessed. Now that 1,000 American surgeons had found it well worth while to come to England to see how the distinguished surgeons of that kingdom did their work, he could say "honors are easy."

Dr. George Emerson Brewer of New York City, the retiring president, was unavoidably absent and in his place Dr. W. L. Rodman of Philadelphia read a paper, which dealt mainly with the College of Surgeons recently established in North America. He pointed out that, stimulated by visits to various clinics of America and other countries, the American College of Surgeons had come into being. It sprang as naturally from the loins of the Congress as the latter was the child of the American Clinical Association. He remarked that it was founded on the admirable lines of the English Royal College of Surgeons and that it could not fail to fill any but an honorable rôle in the standardization of surgery throughout the world. After referring in eulogistic terms to the report of the work of the Colleges of Medicine and Surgeons of England by their joint secretary, Mr. Hallett, Dr. Rodman concluded by expressing the hope that the American College of Surgeons might follow as closely as it could follow the venerable Royal College of Surgeons of England with "a wet sheet, a flowing sail, a wind that follows fast."

The really scientific part of the session then commenced by the reading of a paper on "The Choice of the Operative Method in the Treatment of Ulcer of the Stomach" by Professor Freiherr Anton von Eiselsberg of Vienna. Dr. von Eiselsberg summarized the results of his own and his co-workers' observations as follows: "(1) Symptoms of perforation of the ulcer into the general peritoneal cavity call for immediate operation, irrigation of the peritoneal cavity, closure of the perforation and in bad cases, jejunostomy in addition for the purpose of administering nourishment. (2) In the other complication of ulcer which we fear so much, viz., hemorrhage, operation in most cases is best left alone. (3) In typical stenosis of the pylorus, especially when in the case of a long standing ulcer no new symptoms have occurred, gastroenterostomy is the operation to be chosen. Sixty per cent. of all cases of stricture of the pylorus are completely cured by gastroenterostomy, while in the case of open ulcer gastroenterostomy is only successful in 41 per cent. of cases. Among 334 gastroenterostomies for ulcer of the stomach and duodenum and its complications, 17 deaths occurred. Of these 8 (nearly one-half) occurred through continued bleeding from the ulcer, therefore gastroenterostomy is not in all cases a complete protection against continuance of hemorrhage. (4) Unilateral pylorus exclusion, which I did first in 1894, offers the greatest security in dealing with ulcer and its complications. It should receive special consideration if the ulcer is still fresh and causing much pain and finally in cases of duodenal ulcer it seems to offer a better guarantee of stopping hemorrhage, even though this guarantee is not complete. (5) For ulcer situated at a distance from the pylorus simple gastroenterostomy is not so feasible as in cases of ulcer of the pylorus itself. This my pupil, Professor Clairmont, was the first to show on the evidence of the collective experience of the clinic. It offers only 34 per cent. of successes as contrasted with 54 per cent. of successful cases of pylorus ulcer. (6) High hydrochloric acid values of the gastric juice by distinctly favoring the development of post operative peptic ulcer detract very much from the value of gastroenterostomy and exclusion. (7) I have seen this post operative peptic ulcer after operation done by myself and my assistants in the hospital, as well as in patients who had been operated on by other surgeons, so that the growth of such an ulcer cannot have

been attributed to our perhaps faulty technique. The danger of the formation of peptic ulcer lies under the cases of high hydrochloric acid, especially in such cases where gastroenterostomy was not strictly indicated. There are cases in which the history of the patient given by himself points to a gastric ulcer, but in which the signs of gastric ulcer are wanting at the laparotomy. There may be, perhaps, merely a relatively small stenosis of the pylorus, some adhesions or cicatricial tissue in the stomach. In former years it was more easy to decide on gastroenterostomy in such cases. One regarded it as a safety valve, also as a prophylactic against a stenosis occurring later and therefore more serious. Since H. Braun made us familiar with the serious complication of post operative peptic ulcer of the jejunum great care is necessary with reference to it. In cases when by necropsy *in vivo* I have found no tangible condition to indicate what one had expected to find, judging from the history of the case, and nothing to show what sort of ulcer it was, I have done simple exploratory laparotomy and have refrained from doing what we may term a "concession gastroenterostomy." Among 16 cases of post operative peptic ulcers of the jejunum which I have seen following gastroenterostomies performed in my own clinic and some by other surgeons, a whole series of measures, some of them very complicated, attempted to reproduce normal conditions, only 2 patients were cured, 4 improved, 3 unknown, 2 unrelieved, and 5 died. So that we see that peptic ulcer is a very serious condition. (8) In cases of ulcer situated at a distance from the pylorus, as well as in cases where there is a high hydrochloric acid value, transverse resection seems to me the operation of choice, as this of all other resections, as for instance, extirpation methods of operation, gives the best security against subsequent complications. It must be made whenever there is the least suspicion that the tumor under consideration may be of a malignant nature. Of 269 patients on whom gastroenterostomy was done at my clinic, and who could be kept under observation for some time after, 41 died at a later stage of the disease, 13 from carcinoma, while 6 died with continuance of the symptoms of the ulcer. These later deaths speak decidedly in favor of the radical operation. Transverse stomach resection is also the correct operation when the ulcer has invaded neighboring organs, as nothing except removal of the ulcer will be of any real assistance. Transverse resection as planned by Riedel, also warmly advocated by Küttner, is a relatively safe operation. We have up to January, 1914, done 11 transverse resections, to which 6 more can be added up to July 1, making 17 in all and not a single death. I have never seen a peptic ulcer or any other harmful result from this operation. When transverse resection cannot be done Method Billroth II should be employed. Method Billroth I is the third in order to be considered. Partial excision is to be entirely rejected. In extreme cases only when other operations are not feasible jejunostomy may be considered, as has been suggested already in cases of perforated ulcer when the patient is so weak that he must be fed immediately after the operation. Jejunostomy makes it possible for nourishment to be given even on the operation table. Further, in cases of peptic ulcer in which for exceptional reasons excision is not possible, it is the easiest and most rapid of all operations for gastric ulcers and above all it leaves the stomach undisturbed. As it has only been done in extreme cases one cannot wonder it has met with so little success and that it is noticeable that so many cases of peritonitis have been associated with it. They were patients whose peritoneum had lost its powers of resistance."

Sir Watson Cheyne discussed this paper or rather gave his views on the operative treatment of gastric ulcer. He laid down three requirements of treatment, rest of the organ, avoidance of chemical irritation, and nourishment of the system. He did not appear to be strongly in favor of gastroenterostomy but recommended gastrostomy as it eliminated movements of the stomach. By the insertion of a tube acid was carried off and the stomach was given time to heal.

Dr. James Sherren, of London, dealt with the subject at very considerable length. He drew attention to the fact that the operation to be performed in the treatment of gastric ulcer could only be decided upon after the abdomen had been opened. His contribution to the discussion was based upon a personal operative experience of 200 cases of chronic gastric ulcer, and 224 cases of chronic duodenal ulcer. The treatment of chronic duodenal ulcer consisted in unfolding the ulcer when it was in its usual situation on the anterior wall and doing post gastrojejunostomy. In the series there were four deaths, all in men over 60 years of age, three from broncho-pneumonia, and one from acute edema of the lungs, twenty-four hours after operation. The results of gastrojejunostomy in this condition were, in his experience, unequalled by any other operation. All surgeons who have had a wide experience of the treatment of gastric ulcer had found that gastrojejunostomy failed to bring about healing in certain cases, and that relapse occurred in many of those operated upon by excision alone. He was convinced that gastrojejunostomy alone so modified gastric conditions that ulcers healed, and that only when complications had arisen was excision or partial gastrectomy necessary. His present practice was to perform gastrojejunostomy in every case, the posterior vertical, no loop operation by preference, or, if this was impossible from adhesions, or the situation of the ulcer, the anterior no loop operation, which he first carried out ten years ago. After excision alone recurrence of ulceration was common. It should never be done except as a complement to gastrojejunostomy When there was indication for excision, and the ulcer was large, Sherren believed that partial gastrectomy was preferable to simple excision and gastrojejunostomy. In no instance had he found it necessary to practise any method of pyloric exclusion, nor did he believe in the view that every chronic ulcer should be excised on account of the possibility of becoming malignant. When hour-glass stomach had supervened gastrojejunostomy on the central side of the obstruction, single if there was one obstruction only, double if two, was the most satisfactory operation. The indications for excision or partial gastrectomy were the same as in ulcer without this complication. Acute perforation of a chronic gastric ulcer was a rare event which should be treated, if the condition of the patient admitted, by closure or excision of the ulcer, followed by gastrojejunostomy. Hemorrhage in chronic ulcer called for operation as soon as possible after first attack, usually within twenty-four hours. The ulcer should be directly treated by ligature of the vessels on each side of it, by inversion or excision followed by gastrojejunostomy. Treated

on these lines the results of the operative treatment of chronic gastric ulcer, both immediate and remote, were excellent. Among 200 cases, excluding those in which perforation had occurred, but including those in which the immediate indication for operation was hematemesis (eight cases, one death), there were six deaths.

The results of cases operated on over two years by all methods were briefly as follows: One hundred and twenty-one were operated on over two years ago, with four operative deaths; 109 of the survivors were traced for over two years; 99 of these remained perfectly well, five were better, but not quite well. Only one received no relief.

There was no difference whatever in the results in those operated on for ulcer at a distance from the pylome and those at the pylome, or in those in which the ulcer was excised in addition to gastrojejunostomy. In conclusion the speaker would say that gastrojejunostomy still remained the operation of choice in chronic gastric ulcer; it was only when complications had arisen that gastroenterostomy had to be added to the operative procedure.

The next event on the programme was the presidential address by Dr. J. B. Murphy, who took for his subject, "Arthrodesis and Bone Transplantation." As American surgeons are well acquainted with Dr. Murphy's work, only the main points of his address will be given. He insisted that in the case of ankylosed joints, prophylaxis was of more importance than treatment. Infection originated in two tissues, in the vascular layers of the synovial membrane and the bone end, metastasis took place either in one of these two tissues. Infection rarely occurred on the surface of joints. Metastasis was conveyed by the blood vessels. Acute infection did not originate in the joint. A chill was the primary danger signal. Rheumatism, so-called, was never a primary infection. One of the difficulties of tracing the infection was that a long period elapsed between primary infection and manifestations in the joint. Neisser's infection manifested itself from 18th to 22d day after primary infection, the cycle of metastasic. Streptococcus infection was manifested in the early days of recrudescence of the disease and not in the early stage, and that was the reason why there was difficulty in connecting the primary infection with the joint lesions. In arthritis the organisms were held in the joint fluid in swarms. When the joint fluid was aspirated they were found in large numbers. Prophylaxis came in to prevent disintegration of the joints. Three points had to be considered: (1) Violence of infection. (2) Tension in the joints. (3 Articular pressure in the joints. The means to avoid ankylosis were to relieve tension of the joints. To achieve this object careful technic was necessary. If you opened the joint and exposed the serous membrane you would have destruction of the endothelial cells, and if you drained the joint you would produce ankylosis. The joint might be incised and the products of infection permitted to escape thus relieving tension, but the joint must be immediately closed. The joint might be washed out and closed. The joint might be aspirated and the aspiration might be repeated as the fluid reappeared. The violence of infection might be minimized by injecting into the joint. For this purpose, turpentine seemed to be the ideal substance, but was not available because we could not control it without destroying tissue. The best known substance was formalin 1-3 per cent. in glycerol. A fluid could be produced in the joint which was opposed to the growth of microorganisms and would bring about the highest polynuclear cytosis that could be effected. When high pressure and inflammation were present in the joint the cartilages became softened and contact with the bony end was the result. What could be done to prevent this? We must occasion separation of the bony ends. Surgeons were considered responsible for the deformities of joints caused by injury, but were not considered responsible for the deformities occasioned by arthritis. In order to control the deformities of arthritis they must be taken in hand immediately. If allowed to persist deformities became ineradicable. The first step in this direction was to place the limb in correct position for subsequent use. With regard to arthoplasty Dr. Murphy declared that a movable sliding joint could be made. This had been contradicted, but if in 100 cases you had one successful case it showed that it could be done, and its accomplishment was a matter of technic and asepsis. As for ankylosis of the jaw, operation should be performed on the side opposite to that on which flattening had occurred. The hip joint was the easiest for the surgeon to reconstruct, and the knee joint the most difficult, but the latter gave the more satisfactory results. Operation on the knee joint should be performed with the knee hanging over the edge of the table. The surgeon's hand must never be placed in the cavity and the normal conformation of the knee must be preserved.

1. Cesarean Section. An Historical Review, With an Analysis of Sixty Cases. T. F. Greene.
2. The Fasting Metabolism of Infants. H. Murschhauser.
3. Myatonia Congenita, with Report of Cases. C. H. Dunn.
4. Three Unusual Cases. R. M. Green.
5. Pneumothorax for Hemoptysis. E. von Adelung.

1. Cesarean Section.—T. F. Green reports a series of sixty cases in which this operation was performed. One mother died. There was no fetal mortality. Of the mothers, 4 were under twenty years of age; 13 were from twenty to twenty-five years old; 13 were from twenty-six to thirty years old; 14 were from thirty-one to thirty-five years old, and 16 were from thirty-six to forty years old. There were 34 first, 16 second, 1 third, 5 fourth, and 4 fifth pregnancies. Of the sections, 51 were first and 8 were second sections, and 1 was a third section. The following were various indications: Eclampsia with varying degrees of justo minor pelves, 7; eclampsia with large baby (nine pounds) in primipara, 1; malposition of uterus after Alexander operation, 1; old tuberculous anchylosed hip with deformed pelvis, 2; placenta previa complete in primipara with justo minor pelvis, 1; chronic heart with general edema plus pelvic deformity, 1; primiparous twin pregnancy with breech presenting in flat pelvis, 1; flat pelvis, 17; varying degrees of justo minor pelves, 29. The author emphasizes the fact that the Cesarean operation should be an operation of election. This means that the obstetrician puts himself in the position of a prophet foretelling the outcome of labor. It is true that he may be criticized, but his results will be far more satisfactory to mother and child than if he puts his trust in chance. Opening the abdomen of a woman exhausted by long labor and exposed to the risk of infection is a task from which any operator may well shrink; but if for religious reasons, one recognizes that the child in utero has a

right to life, there is left open no other method of delivery, and its results justify the wisdom of the choice.

3. **Myatonia Congenita.**—C. H. Dunn reports three cases of this condition which was first described in 1900 by Oppenheim. The disease is characterized by a limitation of active movement, varying in degree, which in the most marked cases apparently reaches a complete paralysis, the extremities lying motionless. Although on close observation contractions may be brought out in some of the muscles, they are weak and without locomotor effect. In Oppenheim's cases the lower extremities were always more markedly affected than the upper, and the muscles supplied by the cranial nerves were not affected at all. The muscles of the neck and trunk were affected in one case. In none of his cases were the muscles atrophied, although they were soft. Electrical stimulation showed a varying diminution of contractility up to complete disappearance. There is no disturbance of sensation, and there is no reaction of degeneration. There is a very marked relaxation of the joints, owing to the flaccidity of the muscles. The affection is congenital, though it may not attract attention for some time after birth. Oppenheim considers the condition to be essentially one of retarded development of the muscles, and that it tends to betterment, although he does not exclude the possibility of involvement of the nerves or spinal cord. Since 1900 about forty cases of this condition have been reported, and all the main points in their symptomatology are covered by Oppenheim's original description. It seems that the disease is toxic rather than infectious. The author believes myatonia congenita is much commoner than is generally supposed.

5. **Pneumothorax for Hemoptysis.**—E. von Adelung notes that the value of induced pneumothorax to control bleeding from the lungs is hardly sufficiently appreciated. The medical treatment involves considerable loss of time and subjects the patient to the unpleasant and often harmful by-effects of the drugs used. This is especially true of opium, the most valuable of the drugs used for hemoptysis. Pneumothorax, on the other hand, acts promptly and obviates the disadvantages of drugs. For the purpose of inflation the author uses a portable apparatus modeled after Murphy's original apparatus. More recently Murphy has suggested a simple procedure which consists in introducing a hypodermic needle into the pleural space and allowing atmospheric air to be sucked in until the patient feels distress. The needle is dulled by rubbing it on a stone, the skin is cleansed, a puncture of the skin is done with any sharp instrument, and the boiled hypodermic needle is then inserted into the pleural sac with its outer end covered by sterile absorbent cotton which filters the air that passes in.

1. **Typhoid Fever in Early Life.**—J. P. Crozer Griffith describes this disease as it occurs in infancy, in early childhood (two to six years of age), and in later childhood. The division is of importance because the symptoms, course, and prognosis vary with the three different periods of life. The onset in infancy is decidedly shorter than at a later age. It may be roughly stated as lasting from three to four days before the fully developed attack is reached, this being marked by the appearance of the roseola or by the fever reaching its height. The temperature rises rapidly and is often at its height when medical aid is first summoned. There is rarely seen the steplike rise of the adult type. Vomiting is a frequent early symptom and in some cases is very troublesome; while diarrhea is oftener observed than at later periods of life and is probably more frequent than constipation. After the attack has reached its height vomiting is comparatively frequent; diarrhea continues to be oftener seen than constipation; coating of the tongue is common, but dryness and fissuring are very exceptional; there is not much loss of appetite, this depending perhaps upon the presence of thirst; abdominal distention is frequent but not troublesome. Comparatively uncommon are such nervous manifestations as decided dullness, apathy, or unconsciousness; and only in the severer cases is there marked prostration. The roseola is perhaps as frequently seen in infancy as later. The temperature is not characteristic and many variations are witnessesd. In early childhood one expects the attack to run its mildest course. The onset is not as sudden as in very many cases in infancy but nevertheless is often short and abrupt. In most cases the onset is insidious, with symptoms so little marked that nothing of importance is suspected until perhaps the roseola and enlarged spleen are found. In the eruptive stage there is generally an absence of the evidences of the typhoid state so common in adults. In later childhood the disease gradually approaches the adult type more and more as puberty is approached. This is especially true after the age of ten years. Diarrhea is now often troublesome, the result of the greater degree of intestinal ulceration present at this time of life. Hemorrhage and perforation are more liable to occur than earlier. The symptoms of the typhoid state are more likely to develop, yet not to the extent seen in adult life, and only in severe cases. The course is longer than before, frequently equalling the ordinary four weeks of the adult, and the temperature of the third stage is often more of the remittent type.

3. **Constitutional States in Relation to Gynecological Conditions.** By R. S. Morton. (See MEDICAL RECORD, July 25, 1914, page 185.)

6. **Eosinophilia in Chorea.**—S. S. Leopold presents a preliminary report which indicates the following: Eosinophilia is present in the majority of cases of true Sydenham's chorea. It is present almost invariably in recurring cases, especially where there has been more than a single recurrence. Because of the limited number of cases studied, this observation must be taken tentatively, pending future and more exhaustive study. The absence of eosinophilia in every case in which the diagnosis of true chorea was in doubt may prove of some diagnostic significance in borderline and doubtful cases. The presence of eosinophilia in the majority of cases is in favor of the theory of the infective origin of chorea rather than of the theory that chorea is a functional neurosis.

4. **Salvarsan in Non-Syphilitic Diseases.**—W. H. Best formulates the following rules for the use of salvarsan in non-syphilitic diseases: Salvarsan is specific in diseases caused by any variety of spirillum. Salvarsan has curative properties in those diseases in which the infecting organisms are found in the blood or lymph, or in other locations where they can be easily reached. Salvarsan has great therapeutic value in those diseases in which arsenic has been successfully used. Salvarsan if used with caution, in repeated doses over a long period, has a therapeutic value in those diseases in which previously arsenic gave indifferent results. Salvarsan used as an adjunct to some other drug or drugs is useful in those diseases in which a decided and quick tonic, stimulating and alterative effect is desired, depending on the other drug or drugs for the ultimate result. The mode of administration is important, and should be as follows: intravenous in those diseases in which a specific action is desired; full dose muscular injections repeated once or twice at long intervals (eight weeks), in those cases in which the tonic, stimulating, and alterative effect is desired, as well as a certain specific action; small, oft-repeated (week or ten days) doses, intramuscularly, over a long period of time, in those chronic diseases in which a purely tonic, stimulating, and alterative effect is desired.

5. **Experimental Chronic Gastric Ulcer.**—J. C. Friedman and W. W. Hamburger conclude from their experiments on dogs that chronic ulcers may arise from acute ulcerations, if certain factors are present, namely, prolonged and probably violent action of active gastric juice, that is, hypersecretion and hyperperistalsis, and that such ulcers may remain unhealed if the acidity later drops to normal. Other factors, such as anemia, absence of antipepsin, vascular obstruction, etc., are unnecessary presuppositions. Stromeyer's theory of the digestive action of the gastric juice and the progress of food particles as determining the typical shape of ulcers is probably correct. The majority of chronic ulcers are single and situated near the pylorus, because ulcers elsewhere tend to heal, the factors causing chronicity being usually present only near the pylorus.

9. **Cases of Sprue Invalided from the Tropics.**—By H. B. Hiatt and W. Allan. (See MEDICAL RECORD, June 27, 1914, page 1187.)

10. **Diphtheria of the Skin of Unusual Types.**—F. C. Knowles and L. D. Frescoln state that diphtheria of the skin may occur in several forms, in addition to the false membrane type: the ulcerative, gangrenous, eczematous, impetiginous eczema-like pustular, impetiginous, ecthymatous, vesicular (varicella-like), bullous, dermatitis herpetiformis-like, tumors and abscesses. The authors' two cases were of the bullous impetigo type, one terminating fatally. Inoculation of the skin occurs by autoinoculation, by means of infected articles, and from one person to another. It may occur primarily on the integument, remain limited to it, and spread to the mucous membranes, or, more commonly, it is secondary to throat, nasal, or laryngeal diphtheria. In cases of diphtheria of the skin the Klebs-Loeffler bacillus always has to be distinguished from the pseudodiphtheria bacillus. These two organisms differ somewhat morphologically, culturally, and in animal inoculations. The diphtheria bacillus is particularly distinguished by the metachromatic granules as shown best with the Neisser stain, by the acid producing qualities, and by the fatal results on inoculating animals. The diphtheritic skin lesions are a constant source of contagion, because they are frequently unrecognized for a considerable period. They may last over a long period or run a rapidly fatal course.

1. **Localization of Motor and Speech Centers.**—E. Dupuy states that lesions of both hemispheres in almost the same ratio cause paralysis on the opposite side of the body. In the first 600 cases of hemiplegia which the author has collected 260 showed lesions in the right hemisphere, from which fact he concludes that there is no difference in the functions of the two halves of the brain. Numerous operations performed by surgeons to remove the cause of convulsions or contractures, show that the so-called motor centers for the arm, for instance, or the hand having been removed, not only the convulsion or the contracture disappeared, but no paralysis ensued. Seven years ago Marie tried to show that aphasia is composed of different conditions—one the loss of power of pronouncing words, and the other the loss of comprehension and understanding, or sensory aphasia, so-called. He endeavored to establish the seat of the real lesion of aphasia in that part of the temporoparietal lobe which he defined in a quadrilateral space, including Wernicke's convolution and deeper parts. The author offers the explanation which he believes is the rational one of the mechanism of symptoms in brain lesions. He states that the conception of the seat of definite function, as the doctrine universally adopted will have it, is erroneous. In the light of the examples which he has reported it appears that there are no supplemental centers, but that the entire cortex is endowed with the faculty of acting in specific and differentiated manner, and that at most disease or destruction of a given area brings on motor paralysis or aphasia by an inhibitory influence. This inhibition

would naturally imply alterations of the muscular sense.

4. Celluloid Splints in Acute Poliomyelitis.—F. E. Batten shows that early splinting of cases of acute poliomyelitis with celluloid splints is attended with good results, in that it has aided the recovery of the paralyzed muscles by keeping them at rest, that it has prevented deformity, and has enabled the patient to walk. Of the twenty-four cases of acute poliomyelitis seen and treated within three months of the onset, in twenty-one it is known that no malposition has arisen; three cases have not been seen recently, so no positive statement can be made in regard to them. In one severe case after wearing splints for a year, recovery was so far complete that splints were no longer required, and a year later it was difficult to say that there was any residual paralysis. It is fully recognized that this is fortuitous, and under other forms of treatment the boy might have made an equally good recovery, but it seems certain that his recovery was greatly assisted by the prevention of deformity in the early stage of the disease. Of the remaining cases all have still varying degrees of weakness, Batten says, but nevertheless they are all able to get about and have no malposition of the limb.

5. Epidemic Catarrhal Jaundice.—E. A. Cockayne states that this disease has an almost world-wide distribution and a definite seasonal and age incidence, and is commoner in some seasons than others. It is still an open question whether the disease is a local one of the bile-ducts and liver or a general blood infection. Recently collected evidence seems to prove that the disease is contracted by breathing in air containing the organism, and close contact is necessary. The disease appears to be most infectious in the prodromal period and in the early stages, but the virus may remain active and be transported to a distance.

8. Surgical Treatment of Streptococcic Arthritis.—J. O'Conor bases his treatment of this condition on the following hypothesis: Acute rheumatism is primarily a joint affection due to some pathogenic germ (streptococcus) conveyed by the blood from an infected tonsil, decayed teeth, or some lesion in the intestinal mucous membrane. The joint invasion is promptly followed by a form of acute arthritis with general toxemia, and the infected joints serve as incubators, where the poison is elaborated and poured into the circulation, and thus conveyed to other articulations and to the cardiac valves. In some cases the joints retain the virus in a latent condition until some chill or other cause rouses it into activity. Holding such views as to causation, it naturally followed that the author should suggest that the term acute infective arthritis be substituted for rheumatic fever, etc., and that the names gonorrheal, pyemic, tuberculous, syphilitic, etc., be retained in order to differentiate the infection peculiar to each. The author makes it a rule to operate in cases which do not promptly yield to medical treatment (sodium salicylate, ½ dram; sodium bicarbonate, 1 dram, every three hours; salines, milk diet, woollen clothing, etc.). All infected joints are opened, flaky turbid lymph is evacuated, free irrigation is performed with warm oxygen water, and drainage-tubes are inserted and retained in situ for three days. Multiple incisions are made into areas of periarticular cellulitis and hot mercurial fomentations are applied. Splints are employed for immobilization purposes for from seven to ten days, at the end of which the patient is requested to commence graduated active movements. When the wounds are healed, O'Connor says, gentle massage should be prescribed.

1. The Serum Diagnosis of Pregnancy and of Cancer.—A. Leitch in summing up the results in 100 cases tested to prove the diagnostic worth of the dialysis reaction in pregnancy, finds that by the most generous reading possible, judging by two sets of experiments and not by the usual one, and making allowances for all the hypothetical fallacies that there are, still seventeen most glaring mistakes in diagnosis, which of themselves constitute a large percentage, sufficient to destroy the diagnostic worth of the reaction. But if one applies to the good results the same code of ethics by which one rejects the undesired, then the whole theory becomes worthless.

4. Sprue.—P. H. Bahr concludes that sprue is a specific disease of tropical and subtropical countries, though it is possible that cases occasionally originate in temperate zones. It is a prevalent disease in Ceylon especially among the Europeans. Contrary to the opinion hitherto held, it occurs among the natives irrespective of race or mode of life. This fact, together with the occurrence of the disease in people closely associated with one another, suggests some local influence or some communication of the specific cause from man to man. Sprue is a variable disease. It may occur in a mild or in a particularly virulent form, and, in common with many other serious diseases, is prone to sudden exacerbations, remissions, and periods of latency. There is evidence that the disease may occur in distinct clinical forms, according to the portion of the alimentary canal attacked. Researches in the composition of the stools point either to a complete absence or to an inadequacy of the intestinal digestive ferments. Researches on the blood and on the urine suggest that certain of the more important clinical features of sprue are dependent on an alimentary toxemia. The pathological findings are also in favor of such a conclusion, and, if anything, point to an invasion with the thrush fungus as being concerned in their production.

Berliner klinische Wochenschrift.

July 13 *and July* 20, 1914.

Atypical Gout.—Goldscheider writes a serial article on this subject which he is able to condense into comparatively few words. The so-called gouty metabolism is an extremely common affection, but its highest expression, which we call typical gout, is but a small fraction of the whole. When this does appear there are usually phenomena which suggest plainly a diathetic state, resulting so to speak from the extreme aberration of the gouty metabolism. In atypical gout we do not behold any evidences of a diathesis, save in the metabolism, which indicates unusual burdening of the alimentary organs—which are unequal to the maintenance of normal nutrition—and an incomplete consumption of energy. These changes from the normal also constitute the gouty diathesis. The therapy of atypical gout differs from that of the typical form. The departures from normal metabolism are sufficient to determine numerous disorders of the nervous, circulatory and renal systems, which are sufficiently analo-

gous to the conditions seen in gout proper. A treatment based on correcting the metabolism, which would not alone reach actual gout, is of great service in the atypical form. This consists on the one hand of a correct diet, such as is well known to all practitioners as indispensable in uric acid calculi, "lithemia," etc.; and on the other hand of measures directed against the abdominal plethora so commonly encountered. To sum up the leading symptoms of atypical gout, these include obesity, enlarged liver, neuralgia, myalgia, arthralgia, high blood pressure, tendency to arteriosclerosis and changes in the myocardium; last of all is the tendency to gouty kidneys. Atypical gout while a much milder affection than true gout, is none the less well able to set up fatal disease of the heart and blood vessels and kidneys. Tophi have often been seen in atypical gout.

Relations of the Thymus to Graves' Disease.—Matti concludes a long serial article on this subject. His conclusions, set forth at great length, show that his attitude is chiefly speculative, although numerous facts upon which it is based are of interest. With Graves' disease we commonly find an enlarged, hyperplastic thymus. This does not represent mere coincidence. The enlarged organ may, however, be isolated, or be one element of the status thymico-lymphaticus. The enlarged thymus potentizes the ill action of the thyroid in Graves' disease, yet it does not appear that an enlarged thymus *per se* exerts an deleterious action on the body. Such enlargement is sometimes compensatory, the thymus acting vicariously for the medullary tissue of the adrenals when the latter are hypoplastic. The fact remains, however, that in Graves' disease hyperplastic thymus is part of the syndrome. Experiment produces results opposite to those which one would expect. It is not justifiable to associate hyperplastic thymus with the condition known as vagotonus, which has by some been made responsible for Graves' disease. Vagotonus comprises subjective heart disturbances without corresponding objective finds, sweating, diarrhea, digestive disturbances, pronounced picture of Graves' disease, and finally a high degree of myasthenia. An enlarged thymus forms *per se* no contraindication to operation for Graves' disease; in fact, if the thymus is large and the thyroid not greatly involved, operation on the thymus is indicated. If the adrenals are hypoplastic, experience shows that adrenalin should be given as a preliminary to operation on the thymus. We are at present justified in the belief that Graves' disease is not due entirely to the thyroid. We commonly find associated changes in both glands and a peculiar blood picture.

Experimental Pneumonia.—Meltzer in his report on recent work carried out at the Rockefeller Institute on this subject gives the actual results obtained as follows: Various species of microorganisms of proved virulence were conveyed directly into the bronchial tubes by intrabronchial insufflation. The first trial was made naturally with the pneumococcus. All virulent germs gave a distinct pneumonia reaction, varying much in degree. Heat-killed pneumococci caused a simple transient hyperemia. The right lower lobe was usually the seat of the inflammatory lesion. The reaction varied in extent almost directly with the number of bacilli injected. The germs were found virulent in the exudate during the first forty-eight hours, the latter containing but little fibrin; and could also be cultivated from the blood during the same period. Unless the animals had perished in the meantime, the germs showed complete loss of virulence by the third day. The fatalities were about 16 per cent. The same lesion could be caused by streptococci, but much less readily; while the exudate had a slightly purulent quality. Insufflation of pyocyaneus cultures appeared to poison the animals promptly before any lung focus could have developed.

Münchener medizinische Wochenschrift.

July 14, 1914.

An Exciter of Coughs and Colds.—Kruss believes that the various microorganisms which are apparently capable of setting up acute rhinitis cannot explain certain phases of the latter. In certain cases pathogenic bacteria may be found in the nasal mucus in such small quantities that they cannot be regarded as responsible. This, in fact, is rather the rule than the exception, and in turn tends to throw doubt upon the contention that an ordinary cold is due to the various germs at present accused, as the *Micrococcus catarrhalis*, the influenza bacillus, etc. A simpler and more probable view is that a cold is due to some ultramicroscopic filtrable virus, for during the past twenty years about that number of diseases has been brought etiologically under this head. The writer filtered some nasal secretions of a patient with a cold through a Berkefeld filter and inoculated a considerable number of individuals with the filtrate. In from one to three days all had developed colds. The disease was then propagated through other series. The filtrates were sterile as far as our known germ life is concerned. The invisible offender, thought to be a protozoon, he regards as responsible for most of our colds.

Magnesium Treatment of Tetanus.—Stromeyer, assistant of Lexer, has had very poor results from this aspect of therapeutics. There was but one recovery in five cases. There was no doubt as to the immediate results of the method which sends the patient into a deep sleep and causes notable relaxation of the muscles, but the contractions again light up, and in any case death occurs early from pneumonia and heart failure. Two of the patients had severe pneumonia when admitted for treatment. The series of patients is a most peculiar one in that tetanus did not cause death directly in a single case, while indirectly it can only be said to have been a contributory cause. The author does not appear to accuse the magnesium. To give the latter a full trial, no other remedy was employed. He gave the drug in moderation, and claims that in none of the cases was there any evidence of respiratory failure. In regard to the double pneumonia, one wonders to what extent it was hypostatic. To sum up, it is certain that none of the patients could have died from convulsions because these had either greatly diminished or ceased outright long before death. The fact that in all deaths the autopsy finds were about the same—double pneumonia, acute dilatation of the heart, pulmonary edema—shows a common type. The patient who barely recovered also went through double pneumonia and severe acute decubitus. The anesthetic action of magnesium below the puncture point was notable. One can hardly escape the conclusion that the treatment contributed to the demise of these patients, despite the author's stout denial.

Congenital Milium.—E. G. Graham Little reports the case of a male infant aged three months whose condition as seen had been noted at birth and had increased since then. At the present time the patient had a very copious eruption on the face, especially on the chin, where the whole surface was closely studded with the characteristic small white tumors, in the axillæ, and on the chest, back, and scalp, there being many hundreds of the lesions. The mother had no milium, and this was the only child affected.—*Proceedings of the Royal Society of Medicine.*

Insurance Medicine.

Heart Irregularity and Life Insurance.—Dr. J. S. Lankford, Medical Director of the San Antonio Life Insurance Company, writing in *Salic*, May, 1914, points out that almost all about the heart must be rewritten to conform to the valuable information obtained in the past few years by better methods of investigation. He states that the supreme test to aid in determining the gravity of the situation is to try out the integrity of the heart muscle by exercise and blood pressure tests. If the condition of the heart seems at all suspicious, the blood pressure, diastolic and systolic, should be taken and then the applicant should be made to exercise to the equivalent of climbing two ordinary flights of stairs. If there is serious disease he will come back breathless and more or less distressed, with great irregularity and a murmur may be revealed. Take the blood pressure at once and it may be found that the systolic has fallen and the diastolic has remained stationary, creating a small pulse pressure. If the pressure rises it will be found to decline very slowly in a case of serious disease if the test is made every three minutes. In a normal heart the return to the original position will be very prompt.

A New Investigation Into the Mortality of Insured Syphilitics.—The author cites statistics compiled by L. P. Orr, the British actuary, from reports of American and Canadian insurance companies. The material covers the period 1885-1908 and comprises the risks who had presumably recovered from the disease after proper treatment, and second those in which for any reason there was a possibility that syphilis was latent, and who were insured only as substandard risks with increased premium. In the first class there were three grades based on time elapsed between dates of infection and insurance, no one being accepted unless at least three years had expired. The three periods were (1) from 3 to 5 years; (2) 5 to 10 years; (3) over 10 years.

The actual mortality was much greater than the expectation of life. If the latter be regarded as 100 per cent., the percentages for the three groups were respectively 139 per cent., 147 per cent. and 217 per cent. The finds in the substandard class were of the same kind, the mortalities showing high percentages. Deaths from tabes and paresis were fivefold more than the actual expectation.

Two sets of European statistics compiled up to 1904 are also cited, to wit: those of Gotha and those of the Scandinavian insurance societies. The results are evidently less carefully compiled than those of America but show excess of syphilis mortality to be 68 per cent. and 63 per cent. respectively. The Scandinavian figures go back to 1852. In those regarded as damaged by the disease, the increase is 86 per cent. The Scandinavian material owing to its great age can hardly hold good today, for diagnosis and treatment were both undeveloped and nothing was known of metasyphilis.

The figures from the United States and Canada going back only to 1886 are not open to these objections. At about this period the question "have you had syphilis" first formally appeared on insurance blanks, together with the one relating to nervous affections. These resulted in a better selection of cases. It will be noted that the average mortality of risks in the American countries is 188 per cent. This excess of 88 per cent. is roughly comparable with the figures of the European countries, to the extent of a complete verification. The excess of mortality today with all our refinements of diagnosis and treatment can only be explained by a more careful analysis of the material.—*Blätter für Vertrauensärzte der Lebensversicherung*, May-June, 1914.

The Reporting of Disease.—In an address presented to the Association of Life Insurance Presidents on June 5, 1914, Dr. Louis I. Dublin, statistician, Metropolitan Life Insurance Company, New York, said in part that sickness throughout the country had not decreased, despite a lowering of the death rate. He urged the passage of a bill drafted by the State health officers of New York at a conference in 1913 to ensure complete reports of diseases. Dr. Dublin was of the opinion that the application of sanitary science based on such reports would reduce disease to a considerable extent and be of great economic value to the country. The speaker then pointed out that the amount of sickness has not been controlled to any appreciable degree. The next twenty years must, therefore, see our activities in health work directed especially to the control of disease. The basis for any campaign against sickness must be an accurate knowledge of its prevalence. Just as the reduction of mortality is furthered by a complete registration of deaths and their causes, so our efforts to reduce the frequency of disease depend upon machinery for reporting cases of illness, their causes and their duration. Although most of the States had laws requiring the reporting of some infectious diseases, investigation showed that the reports were almost useless because of incompleteness. Whatever is the explanation, it is quite clear that at present no important aspect of our State health work showed up to such poor advantage as did the registration and control of the preventable diseases. Dr. Dublin outlined a few cases in which epidemics of communicable diseases had been checked by early reporting, including an epidemic of infantile paralysis in Buffalo, which was halted without serious fatalities.

Varicose Veins and Hemorrhoids in Life Insurance.—At a meeting of the British Life Assurance Medical Officers' Association on November 5, 1913, Dr. F. de Haviland Hall said that he had had personal experience of only two cases in which an addition was made on account of varicose veins and these two cases threw no light upon the influence of varicose veins on life expectancy. On this point he could only repeat what he had written in his little book on "The Medical Examination for Life Assurance." In this he said that varicose veins need not be regarded unless they are very large; in this case the risk of rupture and fatal hemorrhage or of embolism must be considered. It has been suggested that from a life assurance point of view varicose veins might be disregarded, but a recent case of death from pulmonary embolism as a result of varicose veins had shown the need for caution. The existence of piles should give rise to the suspicion of commencing cirrhosis of the liver, although, of course, they often occur in people of sedentary habits, suffering from constipation and without any relation to liver disease. Dr. Hingston Fox considered that the great majority of hemorrhoids might be taken at ordinary rates and that varicose veins did not materially add to the risk.

Book Reviews.

TASCHENBUCH DER THERAPIE. Herausgegeben von Dr. M. T. SCHNIRER. Zehnte Ausgabe. Price 2.50 Mks. Würzburg: Curt Kabitzsch, 1914.

THIS is the tenth edition of Dr. Schnirer's pocket manual. 45 new drugs are mentioned. Prof. Gaertner, Dr. Hahn and Prof. Knöpfelmacher have contributed additions and revisions, and Dr. Schnirer has included the "Formulae magistrales Berolinenses."

FESTSCHRIFT DES KURMITTELHAUS DER AL HAYAT COMP. IN HELOUAN. Herausgegeben von Dr. WILHELM PREMINGER und Dr. MAX LOEWY. Cairo: Druckerei der Société Orientale de Publicité, 1914.

THIS pamphlet includes articles on nephritis and gout of the knee joint by Dr. Wilhelm Preminger, on hypnosis and the limits of hypnotic influence, and on the climate of Helouan and its indications in certain diseases by Dr. Max Loewy. The Prussian Ministerium sent an expedition to Helouan to make a report on the desert climate, and this pamphlet was issued as a souvenir by the doctors of the Al Hayat Company's Institut Médical.

DIE GONORRHOE DES WEIBES. Von Prof. Dr. F. FROMME. Price 2 Mks. Berlin: S. Karger, 1914.

PROF. FROMME advocates a purely conservative treatment of gonorrhea in women in this pamphlet intended for practitioners. He has devoted some space to the questions of diagnosis and the relative values of therapeutic methods.

DES HAARSCHWUNDS URSACHEN UND BEHANDLUNG. Von Sanitätsrat Dr. S. JESSNER. Price Mk. 90. Würzburg: Curt Kabitzsch, 1914.

THE seventh edition of Dr. Jessner's dermatological lecture on the causes and treatment of falling hair mentions all the new remedies for the various alopecias and their therapeutical values.

DIE REINFECTIONEN BEI SYPHILIS. Von Dr. med. J. BENARIO. Price 3.50 Mks. Halle a. S.: Carl Marhold's Verlagsbuchhandlung, 1914.

DR. BENARIO has collected the cases of syphilitic reinfection which have been observed and published in the French, German, English, American, and Italian medical journals since the introduction of salvarsan. There are 49 cases after salvarsan treatment and 47 cases after salvarsan and Hg treatment. Dr. Benario concludes that the increased number of these reinfections point to a superior sterilization attained by salvarsan since Neisser's animal experiments have proved that reinoculations are only possible in such animals as had been thoroughly cured. Dr. Benario thinks that analogous conclusions may be drawn for men.

THE CLINICAL HISTORY IN OUTLINE. By PAUL G. WOOLLEY, S.B., M.D., Professor of Pathology, College of Medicine, University of Cincinnati; Director of Laboratories, Cincinnati General Hospital, Cincinnati, Ohio. Price $1.00. St. Louis: C. V. Mosby Co., 1914.

THIS little book makes no attempt to take automatically a clinical history. It is intended merely as a sort of reminder of points to be considered and to offer a systematic scheme for arranging the facts concerning a patient. It does not replace the larger works on this subject.

A WAY OF LIFE. An address to Yale Students Sunday evening, April 20, 1913. By WILLIAM OSLER. Price 50 cents net. New York: Paul B. Hoeber, 1914.

THIS is one of the most recent of Osler's addresses and sums up in terse words a philosophy of life. The lesson is taught that man should live in "day-tight compartments." Profiting by the experience of the past and providing for the needs of the future, he should heed the following precepts: "Waste of energy, mental distress, nervous worries dog the steps of a man who is anxious about the future. Shut close, then, the great fore and aft bulkheads, and prepare to cultivate the habit of a life of life of Day-Tight Compartments." "The failure to cultivate the power of peaceful concentration is the greatest single cause of mental breakdown." "The quiet life in day-light compartments will help you to bear your own and others' burdens with a light heart. Pay no heed to the Batrachians who sit croaking idly by the stream. Life is a straight, plain business, and the way is clear, blazed for you by generations of strong men, into whose labors you enter and whose ideals must be your inspiration."

HANDBOOK OF MEDICAL TREATMENT. A Guide to Therapeutics for Students and Practitioners with an Appendix on Diet, by JAMES BURNET, M.A., M.D., M.R.C.P. Edin. Fellow of the Royal Society of Medicine, Lecturer on Practical Materia Medica and Pharmacy, Examiner in Materia Medica and Therapeutics to the University of Aberdeen, Physician to the Marshall Street Dispensary and Registrar to the Royal Hospital for Sick Children, Edinburgh, Author of "The Pocket Prescriber" and "The Pocket Clinical Guide." Price $1.25. London: Adam and Charles Black, 1913.

THIS volume is an unambitious attempt to supply the main facts of medical treatment within the compass of a small book, convenient to handle and to carry about. Purely surgical and gynecological conditions have been entirely omitted. The subjects are alphabetically arranged.

HEALTH PRESERVATION IN WEST AFRICA. By J. CHARLES RYAN, L.R.C.P.I.L.M., L.R.C.S.I., L.M., Diplomate in Tropical Medicine, University, Liverpool; late M.O. West African Medical Staff, with Introduction by Sir RONALD ROSS, K.C.B., F.R.S., Nobel Laureate M.D., D.P.H., F.R.C.S.D.Sc., LL.D. Price, 5 shillings. London: John Ball Sons & Danielsson, 1914.

OWING to the fact that the number of people who are finding employment in West Africa is yearly on the increase and because of the misleading and dangerous statements uttered by some of the "old coasters" the compilations of these hints have been found necessary. As briefly and as simply as possible the essential and personal measures are described towards the preservation of health by those visiting West Africa.

THE HYPODERMIC SYRINGE. By GERRGO L. SERVOSS, M.D., Editor of "Nevada Medicine," Member of the Nevada State Medical Association, Fellow of the American Medical Association. Price $2. Newark, N. J.: Physicians Drug News Co.

THIS book follows in the footsteps of Bartholow's little work on hypodermic medication published several years ago. No attempt has been made to inject anything of an original nature but rather to give a condensed narrative of the hypodermic syringe and its possibilities as set forth by numerous authors and investigators. The wonderful strides made in hypodermic medication in recent years call for the concise and thorough presentation as here given. Some of the subjects taken up are technique, drugs, chemicals, sera, bacterins, anesthesia, etc.

MAN'S REDEMPTION OF MAN. A Lay Sermon, McEwan Hall, Edinburgh, Sunday, July 2, 1910. By WILLIAM OSLER. Price, 50 cents net. New York: Paul B. Hoeber, 1913.

THE gospel of health is the keynote of this sermon written in a forceful and epigrammatic style. The abolition and the prevention of disease are the means whereby man's redemption by man is being accomplished. "In the comedies and tragedies of life," says Osler, "our immutable human nature reacts very much as in the dawn of science, and yet, with a widening of knowledge, the lights and shadows of the landscape have shifted, and the picture is brighter. Nothing can bring back the hour when sin and diseases were correlated as confidently as night and day; and how shall we assess the enormous gain of a new criterion, a new estimate of the value of man's life. There are tones in human sentiment to-day which the ancients never heard, which our fathers indeed heard but faintly, and that without recognizing their significance. The human heart by which we live has been touched as with the wand of a Prospero. What availed the sceptred race, what the glory that was Greece, or the grandeur that was Rome, of what avail even has been the message of the gospel, while the people at large were haunted by fear and anxiety, stricken by the pestilence of the darkness and the sickness of the noonday? The new socialism of science with its definite mission cares not a rap for the theories of Karl Marx, of Ferdinand Lasalle, or of Henry George; still less for the dreams of Plato or of Sir Thomas Moore—or at least only so far as they help to realize the well-being of the citizen. Nor is there need to fear that in weighing the world in our balance we may drain the sap of its life, so long as we materialize in the service of man those eternal principles on which life rests—moral fervor, liberty, and justice."

Society Reports.

BRITISH MEDICAL ASSOCIATION.

Eighty-second Annual Meeting Held in Aberdeen, July 24-August 1, 1914.

(Special Report to the MEDICAL RECORD.)

SIR ALEXANDER OGSTON, M.D., PRESIDENT.

AT the opening meeting of the Representatives it was decided to hold the meeting of the Association for 1915 at Cambridge from July 2 to 10 and Sir T. Clifford Allbutt was appointed president-elect. Concerning the finances a question was asked as to payments made to members of parliament for supplying reports for the *Journal*. Complaint was made by Dr. Beaton of the low salaries paid to some members of the staff and a recommendation to the council for a favorable consideration was unanimously carried. Dr. Haslip protested against the appointment of three new assistant secretaries as unnecessary and therefore extravagant. The financial report was eventually adopted.

It was agreed that the subscription be two guineas for residents in the United Kingdom, and 25 shillings for those in the Channel islands and colonies. A resolution was passed that the annual representative meeting should be deliberative and not bound by proceedings at divisions.

It was agreed on in the proposal of Mr. Turner, representing the Kensington division, to write to the Chancellor of the Exchequer to urge that the petition of Sir Ronald Ross for remuneration for services to the Empire in connection with the investigation of malarial fever ought to be granted. Mr. F. J. Smith said it was a lasting shame on England that medical men at home and in the colonies were let to go into the difficult and dangerous byways of nature and get nothing for it unless posthumous honor. A resolution warned against contributing articles on medical matters to publications issued to the general public. One such was named in which dangerous drugs had been recommended. Steps towards the State registration of nurses were approved.

On Saturday the whole day was occupied by the representative meeting with a report of the council on the proposal to establish a special fund according to instructions of a previous meeting in favor of doing so. The proceedings had been in private as to this, but an official statement was issued to the effect that the proposal was carried by a large majority. It was settled that the fundamental object should be protection of the honor and interests of the profession and the formation of a reserve. The question whether this should be done in the trade union way was decided against that plan—some other method of administration to be employed.

On Sunday (26th) there was a temperance demonstration. Some twenty doctors spoke from Aberdeen pulpits and platforms. Sir Victor Horsley addressed a brotherhood meeting on "Alcohol, the Enemy of Brotherhood," because, he said, it was responsible for poverty, misery, and the destruction of life; some 1,600 persons being poisoned by it every year. There was close association between the drink trade and slums. Housing was one of the most difficult problems, but he expected the great municipalities, when the taxation of land values came in, would be provided with one way of dealing with this complex question, without falling back on that patient ass, the ratepayer.

On Monday the relation of the profession to the State and the Insurance Act was discussed in various aspects, including payments proposed, the danger of doing government work without payment, the alleged desire of the government to control the voluntary hospitals, the right of all insured persons to a free choice of a doctor—whether on the panel or not, the admission into free hospitals of women entitled to maternity benefit. These and similar points occupied a long time. On the other hand much amusement was caused by the speed at which Scottish affairs were rushed through—all the recommendations of the special committee being approved within a minute.

On Tuesday the representative committee held another meeting when other points in the working of the Insurance Act were considered and business of interest only to members disposed of, prior to what may be termed the meetings proper of the association when the decisions for the coming year stated above were confirmed, the gold medal was presented to the chairman of the representative meetings and to the treasurer.

The Presidential Address was delivered by Sir ALEXANDER OGSTON on "The Making of a Scottish Medical School." The president described the steps by which the foundation of the university and its medical school had been laid. It was partially owing, he said, to the Wars of the Roses that the earliest of all British medical schools was established in Aberdeen. At the close of the fifteenth century the state of education and culture in Aberdeen was at a low ebb. In a Bull regarding the founding of the university the Pope (Alexanderd VI.) had stated that the people were so ignorant that persons could not be found who could read the Word of God, preach or administer the sacraments. To the advent of Bishop Elphinstone, about 1483, Aberdeen owed reforms of the greatest importance. As a result of the Wars of the Roses the clergy, who acted as negotiators, possessed exceptional powers, and Bishop Elphinstone gave effect to three great schemes for the benefit of Aberdeen, the restoration of the Cathedral, the provision of a good and practicable access to the city by land, and the foundation of a university. The wisdom of the bishop in respect to the study of medicine was worthy of the greatest admiration. Not a single university in the British Isles had up to that time seriously set itself to establish a teaching medical faculty as part of its machinery. For the profession, or rather the trade, of medicine had sunk very low, particularly in Scotland, and the specimens to be met with there would not have encouraged an ordinary mind to provide a faculty for them in a university. For the post of principal of the university he selected Hector Boece or Boyce, who at the time of the starting of the university was about thirty-three years of age. The medical seed planted by Elphinstone did not at once spring up into full vegetation. The English masters of medicine had not yet arisen, and the scientific foundations on which modern medicine rested were not even begun to be laid. Nevertheless, it was the foresight of Elphinstone that prepared the ground, and his endowments that planted the seed which was afterwards to spring up into the flourishing school of medicine of which Aberdonians had good reason to be proud.

Medicine from the Chemical Standpoint.—Dr. ARCHIBALD E. GARROD of London delivered this, the Address in Medicine, on Wednesday, July 29. He said that many of the early chemists were practitioners of medicine, and from the days of Paracelsus and of van Helmont, the father of physiological chemistry, down to the earlier years of the nineteenth century, the chemical outlook had been that most widely adopted by medical men. Throughout the greater part of the last century morbid anatomy and histology had held the field unchallenged; and they had been justly entitled to do so in view of the progress made in the macroscopic and microscopic study of diseased structures, upon which had been reared the imposing edifice of cellular pathology. Yet, during this period the science of chemistry, both in its inorganic and organic branches, had been making rapid strides. The syntheses of urea by Wöhler in 1828 brought the products of life within the province of the pure chemist, and there had always been investigators who, with Liebig, studied the intake and output of living organisms, and who added to our knowledge of the chemistry of the urine, and of the problems presented by such maladies as diabetes and gout. Carbon compounds of ever greater complexity had been built up, step by step, from their elements, and even the synthesis of proteins was being brought within reach, thanks to the labors of Emil Fischer and of a body of workers who derived their inspiration from him.

Among the building materials employed in the construction of living organisms the proteins held a place apart. They were the actual vehicles of life, and upon their properties the very possibility of life depended. The huge molecules of the proteins had been teased out—to borrow a term from histology—and, as a result, the conception of an unwieldy group of atoms had been replaced by that of an orderly structure composed of comparatively simple building stones, of a neatly constructed block of masonry rather than an amorphous mass of concrete. These building stones were the now familiar protein fractions. Some of them had long been known as rare ingredients of the excreta—such, for instance, as tyrosin, leucin, and cystin—but whence they came and how they were formed in the body had been, until recently, unknown. Widely as the protein fractions differed in their structure, they had this in common—that they were amino- or di-amino-acids. Seeing that they shared the properties of acids and bases, they were capable of combining with each other to

form the complicated chains or networks which constituted the protein molecules; and since they admitted of combination into many different groupings, there was a possibility of almost infinite varieties of protein structure. Abderhalden estimated that the possible combinations of the twenty known protein fractions, in which each individual fraction was represented once, and only once, needed for their expression a number composed of no less than thirteen digits. The very proteins which performed identical functions in different animals were not themselves identical, but differed from genus to genus, from species to species, and differed the more widely the further the several species were separated from each other in the evolutionary scheme. The effect upon physiological thought of this conception of chemical specificity had already been far-reaching. One no longer thought of the proteins of food as utilized, after comparatively slight change, and in such complex forms as albumose and peptone. The differences between the food proteins and those of the animal fed necessitated the assumption that their disintegration by the digestive juices was far more thorough than used to be supposed, and that reconstruction of the proteins in the organism fed started from the primary amino-acid fractions. Moreover, each tissue-protein bore not only the impress of the specific stamp, but also of a second stamp derived from the organ of which it formed part. The recent work of Abderhalden and the study of cytolysins afforded evidence that the proteins of the liver, spleen, pancreas, or any other organ had their special peculiarities. Sulphur was contained in one particularly amino-acid fraction—namely cystin, and an unusually large proportion of sulphur indicated a large cystin content. Phosphorus, on the other hand, was a constituent of the nucleo-proteins, which, as essential constituents of the cell nuclei, might lay claim to an importance second to that of no members of the protein group. In them also was included the purin grouping, the parent complex of most of the uric acid of the urine. As another example of a protein to which a special atomic group was attached hemoglobin called for mention, seeing that, in virtue of the iron-containing hematin which it included, it was able to fulfil the all-important function of carrier of oxygen to the tissues. Each kind of foodstuff, and indeed each individual protein fraction, followed its own special metabolic path. Moreover, there were paths for fats and paths for carbohydrates, and it was evident that even dextrose and levulose were dealt with in different manners, for a patient whose power of burning dextrose was grossly impaired might deal with levulose with far better success. In the same way the power of catabolizing a single protein fraction might be lacking in an individual who was able to dispose of the other protein fractions in a normal manner. It was believed that these changes were wrought by specialized enzymes, many, if not all, of which were capable of reversed action. Thus were produced numbers of intermediate products which were subjected to further changes as soon as they came into existence, and which called to mind a moving staircase rather than a flight of steps. Most of these intermediate products were never met with in an examination of the excreta, or only when the further transformations which they naturally underwent were in some way arrested.

In the course of evolution, a state would have been brought about in which the end products of metabolism would be harmless to the organism in which they were formed; but so delicately were the relations of tissue change adapted to the requirements of the organism that any deviation from health which disturbed the chemical processes, however slight the disturbance might be, led to the formation of products which were less well adapted, and tended to do harm. Obviously, only by a rigid system of control could the orderly working of the intricate metabolic changes be maintained, and the working of regulating mechanisms in the animal body was made manifest in a variety of different ways. In recent years there had been gained some insight into the mechanisms by which regulation was affected, and of the importance in this connection of the internal secretions of glands, ductless and others. However, the internal secretions were implements, rather than originators of control. The hormones were themselves but chemical products of certain specialized cells, and the activities of the glands which produced them were themselves under the control of the vegetative nervous system, which transmitted to them impulses in response to the chemical demands of the tissues. The inborn errors of metabolism were individually as rare as structural malformations, and much more liable to be overlooked. Their scientific value far exceeded their clinical importance, for they constituted true natural experiments. Thus, in cystinuria cystin, and sometimes other protein fractions also, escaped their normal fate, and appeared unchanged or only slightly changed in the urine. In alkaptonuria, on the other hand, there was a failure to complete the breakdown of the aromatic protein fractions, and the homogentisic acid which was excreted was thought, with good reason, to be an intermediate product of normal metabolism.

When into the field of intricate, but orderly, metabolic activities there intruded the agents of disease, a new set of phenomena was brought into action. The entire community bestirred itself to beat off the intruders, and there were called into play protective mechanisms of immense variety. The mechanisms of defence were of various kinds. Some were comparatively simple chemical reactions, as when free acids were neutralized by ammonia diverted from its ordinary path to the formation of urea; or when aromatic poisons were combined with sulphates, and were excreted in harmless forms. But aromatic poisons were also combined with products of protein or carbohydrate metabolism, with the protein fraction glycin to form the harmless hippuric acid and its allies, or with glycuronic acid to form compound glycuronates. Other mechanisms were far less simple, and the very nature of the protective agents was beyond the ken of the chemist. These were the agents known as antitoxins, agglutinins, precipitins, opsonins, and the like.

It was a question of much interest whether or no the various protective mechanisms had been evolved to meet the assaults of those toxic agencies to which the organism was specially exposed, or whether an entirely new mechanism could be devised, at any moment, to meet an unforeseen emergency. Evidence might be adduced in support of either hypothesis. There were many other ways in which derangements of metabolism were brought about by disease, apart from the calling into play of protective mechanisms. When an important organ became the seat of structural changes its functions became disturbed, and their normal orderly working was put out of gear, either permanently or only for a time. In the case of many maladies, even of the more acute and graver ones, the chemical disturbances which they brought in their train were far less conspicuous than the structural changes. In others, again, the metabolic disorders occupied the forefront of the clinical picture, as is the case in those maladies which one was accustomed to group together under the collective name of "diabetes."

There remained to be considered a group of maladies which might be classed as *negative*, seeing that they had their origin in the withholding of some portion of the supplies which the organism derived from external sources, and upon which its wellbeing depended. The extreme example of such a disease was starvation—a condition in which the body, being deprived of its food supplies, lived for a time upon its own fats and carbohydrates, and ultimately upon the proteins of its tissues. Minor degrees of the same condition were induced by restriction of the intake below an adequate calorie value, of proteins below the amount compatible with maintenance of nitrogen balance, or by complete deprivation of carbohydrate foods. The cutting off of carbohydrates, or failure to assimilate them, was promptly responded to by disturbance of fat and protein metabolism, with the result that the substances of the acetone group, aceto-acetic and β-oxybutyric acids were formed and excreted in large quantities. The new study of vitamines and of the effects of a diet consisting of pure proteins, fats, and carbohydrates upon the growth of young animals, was beginning to throw light upon the nature of such factors, "exogenous hormones" as styled by the speaker.

Thus one saw how delicate a matter was the maintenance of the integrity of the metabolic processes in the human body, and how slight disturbing influences might lead to their derangement. One realized how inefficient were therapeutic efforts when compared with the powers of protection with which patients were themselves endowed. It was in the field of diagnosis that the practical utility of chemical knowledge was most obvious.

Perhaps the greatest recent advance in diagnosis by chemical means was the perfecting of methods which enabled accurate and reliable estimations to be carried out, of such substances as glucose and uric acid.

in small quantities of blood drawn from a vein, and even in a few drops of blood from a prick in a finger. Again, the diagnostic methods of Abderhalden, afforded means of diagnosis of a subtlety hitherto not dreamed of, and gave promise of widely extended utility in the near future.

There were scientific grounds for the belief that mankind habitually took more protein food than was required for the due nutrition of the tissues, and undoubtedly the amount exceeded that required for the maintenance of nitrogen balance. As regards details of dietary, the speaker asserted that two-thirds of the restrictions imposed upon sufferers from particular maladies found no real justification in the teachings of science or of experience. One should aim at a diet of adequate calorie value, with due representation of the main classes of foodstuffs. The food should be so prepared as to be easily assimilable, and with due regard to the condition of the patient's alimentary canal. Some at least of it should be in a fresh state, and special restrictions were often desirable in view of defects of excretion, to rest damaged mechanisms, or to limit accumulation in the blood of metabolic products which failed to be dealt with in the normal ways. So, too, as regards treatment by drugs. In default of knowledge of anatomy and physiology, therapeutics could not be other than empirical; but step by step a scientific system of therapeutics was being built up. When one administered a serum or a vaccine, or such a drug as thyroid extract, one was copying Nature's methods, and employing her own weapons. When, on the other hand, the drugs which were employed were toxic substances, foreign to the organism, one should realize that, in giving them, one often produced not only the effect aimed at, but by-effects which could not be fully estimated. Not only were the weapons improved but the progress of knowledge was making one's aim more sure. That the progress of medicine had been more rapid in recent years than ever before was due to the cumulative advance of science as a whole. Modern physics and chemistry, and the borderland science of physical chemistry had rendered possible modern physiology and pathology, and upon the foundations thus provided was being raised the stately edifice of a modern medicine, in which the scientific spirit should have freer play than heretofore.

The Surgeon of the Future.—Sir JOHN BLAND SUTTON of London delivered this, the Address in Surgery, on Thursday, July 30. He said that the art of surgery was probably as ancient as the art of war, and was practised by warlike savages who had never been influenced by civilization. The antagonistic callings of the soldier and the surgeon had been markedly modified by the progress of science. It was believed by many that the ingenuity exercised in the invention of methods for destroying life would make war impossible, and the discovery of the causes of diseases and the perfection of preventive medicine would render physicians and surgeons unnecessary. The belief in each instance was futile. Soldiers and surgeons would be required as long as civilization endured; but their methods had undergone great changes, and greater were impending. Gunpowder revolutionized warfare; the discovery of anesthetics and the invention of the microscope completely changed surgical methods. The arena of an operating theater in the first half of the nineteenth century smacked of the bull ring. When anesthesia began to make progress, although surgeons recognized its importance, many years elapsed before it was fully utilized. Chloroform had been in constant use for operations before its usefulness in the reduction of dislocations was recognized. The utility of chloroform in the diagnosis of hysterical contractures, phantom tumors and spurious pregnancy was its last merit to be appreciated.

The speaker next discussed a subject which he designated as new diseases and the plagues of Egypt. Appendicitis became endemic in great centers of civilization in the last quarter of the nineteenth century. This disease occurred sporadically, and had been known as perityphlitis and iliac abscess for many years, but the cause of the present epidemic had not been discovered by pathologists or bacteriologists. A study of the history of diseases showed that they waxed and waned. In the fourteenth century lepers were common, and leper houses were as numerous in Europe and the British Isles as lunatic asylums to-day. In Europe generally leprosy diminished greatly without any recognized cause in the fifteenth century, but its decline was coincident with a great increase in syphilis. One disease trampled out another. Today one was staggered by the important observations that many infections were conveyed from man to man, man to beast, and from beast to man by insect agency. Flies acted as vectors of the parasites of sleeping sickness, gnats spread filaria, malaria, and yellow fever; fleas infected man with plague, and bugs could convey the leprosy bacillus. The famous plagues of Egypt fraught with such important consequences to the Israelites were intensified by flies. During the last decade they had come to be regarded as a conveyor of disease, and the indictment is very strong. It is not an unreasonable assumption that the death of the Egyptian children, which induced Pharaoah to let the children of Israel go, was due to an epidemic of infantile enteritis spread by an enormous swarm of "divers sorts of flies."

It was usual to ascribe the remarkable progress of surgery to the discovery of anesthesia and the perfection of methods designed to prevent wound infection, but one must not forget that most important was the invention of the microscope; without its assistance the minute bodies which effected such great changes in organic and inorganic nature, and caused so many varieties of infective disease in animals and plants, would have remained not only hidden but unsuspected.

The speaker next discussed the influence of chemotherapy on the surgery of the central nervous system. The effort to arrest the development of bacilli in the blood by means of compounds injected into the cerebrospinal fluid was a method of specific therapy unsuspected in one's wildest dreams. Orr and Rows found that microorganisms used neural lymphatics as routes for infecting the cord. The results of surgical enterprise on cerebral tumors were unsatisfactory; the mortality was great and the condition of the survivors in many instances sad. The indefiniteness of gliomatous formations made them extremely unfavorable for operation, to say nothing of the difficulty in localizing cerebral tumors in nonmotor areas. It was probable that compounds would be discovered that could be injected into the cerebrospinal fluid and cause gliomas to shrivel in the same way that gummas disappeared under potassium iodide, mercury, or salvarsan, and thus abolish some of the most uncompromising operations of modern surgery.

Investigations of the minute structure of morbid growths had been mainly useful in separating the so-called benign tumors from those which inevitably destroyed life. Thirty years ago the two groups were regarded as distinct. It was true that type forms could be distinguished as innocent or malignant, but each genus of the so-called innocent group, with the exception of lipomas, contained species in which the histological features of innocency shaded away into those indicating malignancy.

Cancerous cachexia had no special relation to cancer; it was due to the entrance into the circulating blood of toxic substances secreted by the bacteria and cocci which colonized cancerous growths in exposed situations. This was important to the surgeon, and influenced his work very markedly. As a general rule, nonulcerating cancers of the breast were sterile. Cancer of the tongue usually swarmed with streptococci, and the neck of the uterus when cancerous was colonized by staphylococci, streptococci, or some of the coli group. The author made bacteriological investigations of the neck of a cancerous uterus before undertaking its removal; he found that the fate of a patient submitted to operation for this disease depended not so much on the skill of the surgeon as on the nature of the infecting microorganism. In the general hospitals of London during the year 1912 the mortality of radical hysterectomy for cancer of the neck of the uterus varied from 10 to 48 per cent. This formed a striking contrast to hysterectomy for fibroids of the uterus, for the mortality of this operation in the general hospitals of London was about 2 per cent., the difference being almost entirely due to the presence of bacteria and cocci in the cancerous tissues. The virulence of cancer, as a rule, depended on its septicity, and cancers in exposed situations were rapidly destroyed by bacteria.

The relationship of sepsis and cancer was an important matter for the surgeon. In regions of the gastrointestinal tract free from pyogenic bacteria, union occurred after surgical operations safely and quickly; thus a gastrojejunostomy in the hands of competent surgeons was devoid of risk from septic peritonitis. How different the picture for radical operations performed for cancer of the colon! Septic peritonitis destroyed the lives of at least 30 per cent. of those who

submitted to it. It was by no means uncommon to see surgeons clad in sterilized overalls, gloves, caps, masks, and top boots resecting a cancerous segment of colon swarming with pyogenic microorganisms. This could only be described as surgical coquetry. In order to improve the results of operations for visceral cancer means must be devised for sterilizing them, or a specific remedy found for cancer. There were indications that both methods would be available. What surgeons urgently needed was a molecular compound which would either kill the bacteria and cocci that colonized cancer or neutralize their harmful toxins in the same way that salvarsan rendered spirochetes inert without destroying the organs or tissues of their host.

In pre-Listerian days the path to surgery lay through the dissecting room. A thorough practical knowledge of the anatomy of man had been and was indispensible to a sound surgeon. Surgeons were of two types, they were either craftsmen or biologists. The surgical craftsman invented variations in technique; metal plates, wires and screws for bones; or fancy methods of suturing wounds. Some expended their ingenuity on surgical cutlery. The utility of a simple tool such as the clip forceps was inestimable. In spite of much ingenuity among surgeons, an ideal ligature material awaited discovery. Clever contrivances like the laryngoscope, bronchoscope, and cystoscope revolutionized special branches of surgery. Another useful instrument, the esophagoscope, required for its successful use a surgeon with the instincts of the sword-swallower and the eye of a hawk. The biological surgeon studied pathology in its broadest aspect and investigated into the laboratory problems of morbid anatomy and bacteriology. The diagnostic value of reports issued from the laboratory by the pathologist and the bacteriologist, to be of value, must be estimated with the help of clinical experience. As it was of the utmost importance that surgeons should have a practical knowledge of clinical pathology, it became essential to bring the wards, operating theaters, and laboratories into the closest intimacy. From this union of workers means would be found for curing diseased organs by chemotherapy rather than by extirpating them. The magical effects of salvarsan on the lesions of syphilis, acute and chronic, led one to hope that this compound would assist in the elimination of cancer of the mouth and tongue, for in these situations cancer was often engrafted on chronic syphilitic lesions. In regard to the cure of malignant disease, there was most hope in chemotherapy.

(*To be continued.*)

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

South Dakota State Board of Medical Examiners.

January 13 *and* 14, 1914.

EMBRYOLOGY, HISTOLOGY AND ANATOMY.

1. Describe the maturing and fecundation of the ovum. 2. From what embryonic layer does the respiratory tract develop? What other structures are developed from the same layer? 3. Describe microscopic difference in appearance of heart-muscle and skeletal muscle. 4. Describe microscopically superficial cells lining trachea. 5. Describe the patella. What is its function and how does it functionate? 6. Describe the shoulder-joint. 7. Name the muscles participating in tranquil respiration. 8. Give the blood-supply of the stomach. 9. Give origin and distribution of trifacial nerve. 10. Draw and describe the dorsal surface of the tongue.

PHYSIOLOGY.

1. What is lymph and how formed? 2. What is circulation of the blood? Follow it from and until it returns to the heart. 3. What is the object of circulation? Describe the changes that take place in the blood as it passes through the body. 4. Describe digestion in the mouth and stomach. 5. What is respiration and what causes it? 6. What are the enzymes? Give their chemical composition. 7. Describe intestinal digestion. What juices enter into it? 8. Name the excretory organs. What do they excrete? 9. Name the ductless glands. What are their specific offices in the human economy? 10. How is heat produced and how maintained in the human body?

CHEMISTRY.

1. What use has a physician for knowledge of chemistry? 2. Name ten elements, giving valence and atomic weight. 3. Give chemical name, common name, physical appearance and common use of: (*a*) $MgSO_4$, 7 H_2O; (*b*) Na_2CO_3, 10 H_2O; (*c*) $CH.Cl_3$; (*d*) C_2H_2; (*e*) H_3BO_3. 4. Give chemical name, formula, physical appearance and common use of (*a*) sal ammoniac; (*b*) saleratus; (*c*) calomel; (*d*) corrosive sublimate; (*e*) lunar caustic. 5. What is glycerin? How is it produced? 6. On what chemical substances does hardness of water usually depend? What would you use to soften water? How does that do it? 7. Boil acid urine; if a cloud or precipitate appears, what substances may the cloud or precipitate be? How determine which it is? 8. (*a*) Describe your favorite test for sugar in urine. What are its fallacies? (*b*) Name all the ingredients of your reagent. (*c*) What color change takes place? (*d*) What is the chemical reason for the color change? 9. Give a test for copper in canned vegetables. 10. Is there chemical or pharmaceutical incompatibility in the following prescription? Where is it and why?

℞ Strychninæ sulphatis..... gr. ss (½)
Ammonii chlorid ..... ʒ i
Ammonii carbonatis ..... ʒ i
Aquæ puræ ..... ʒ i
Syrupus pini strobi comp., q.s.ad. ℥ iv
Misce.

BACTERIOLOGY.

1. What is the cause of difference in the virulence of diphtheria? 2. What pathogenic conditions may be produced by the colon bacillus? 3. What is tuberculin? How is it produced? What is it used for? 4. Describe in detail the bacterial findings in puerperal septicemia. 5. How does the tetanus bacillus induce its effect? On what theory is tetanus antitoxin administered?

PATHOLOGY.

1. What is the cause of death following burns? 2. What is thrombosis? Describe the manner of its formation. Where are emboli most frequently found? Of what do emboli most frequently consist? 3. What general pathological lesion characterizes chronic alcoholism? 4. What is ischemic paralysis? 5. State the result of stenosis of the tricuspid valves of the heart. 6. Carcinoma of stomach: Is it usually primary or secondary to carcinoma elsewhere? Where is it usually situated? Give most common type. 7. What conditions may cause dropsical effusion in the abdomen and in the lower extremities? 8. What diseases of the mother may be transmitted to the fetus? 9. Explain the process occurring in necrosis of bone. Give the pathological condition characteristic of necrosis and caries of bone. 10. What determines the benign or malignant nature of a new growth?

ANSWERS.

EMBRYOLOGY, HISTOLOGY, AND ANATOMY.

1. *Fecundation* is the result of the meeting of a live and healthy spermatozoon, with a live and healthy ovum, in a suitable medium (generally the Fallopian tube). During coitus the seminal fluid is ejected into the upper part of the vagina and against the cervix of the uterus; the spermatozoa enter the uterine cavity (either by the suction of the uterus or by their own vibratile motion) and so on to the Fallopian tube. Several spermatozoa may surround an ovum, or even pierce the perivitelline space; but only one spermatozoon enters the vitellus. This spermatozoon loses its tail; and its head becomes the male pronucleus. The male pronucleus and the female pronucleus now fuse together, and fecundation is completed.

Development of the fertilized ovum. "(1) When the ovum is mature, two small cells are detached from the main body of cells; these are called polar globules. It was formerly supposed that these were associated with the disappearance of the germinal vesicle, but recent experiments have demonstrated that the germinal vesicle plays an active part in their formation. This can take place independently of fecundation. (2) The portion of the ovum remaining after the throwing off of the polar globules is called the 'female pronucleus.' (3) Fecundation is effected by the penetration of the head of one spermatozoon. This is called the 'male pronucleus.' (4) The male and female pronucleus coalesce. The ovum is now called the oösperm, or blastosphere.

(5) The *segmentation* of the nucleus and vitellus, *i.e.* they both split into two masses, these into four, and so on until a large number of segments are formed. This is known as the morula, moriform body, or mulberry mass. (6) A clear fluid is secreted within the ovum, which presses these segments to the surface of the ovum, where they form a double layer of cells, differing somewhat in size. The outer and larger is termed the *epiblast* or *ectoderm*, and the inner and smaller the *hypoblast* or *endoderm*. Together they are known as the blastodermic vesicle. (7) There then appears upon the outside of the vitellus a small oval elevation, surrounded by a depression, which is called the *area germinativa*. (8) There appears in the area germinativa a small, dark line called the *primitive trace*. About this line will be grouped the various parts of the embryo, the rest of the ovum serving only as a covering and for nutriment. (9) A covering for this trace or embryo is now formed. Thus far the vitelline membrane has been sufficient. The embryonic line sinks into the center of the ovum, while the edges of the external blastodermic layer about the area close around it, inclosing it in a sac called the *amnion*. Between the amnion and the embryo, fluid at a later period is deposited; this constitutes the liquor amnii. The vitelline membrane then disappears."—(Landis's *Obstetrics*.)

2. The epithelial lining of the respiratory tract is developed from the entoderm (or hypoblast). From the same layer are also developed the epithelial lining of the digestive tract and its glands, including liver and pancreas; also of the larynx, trachea, and lungs; and of the pharynx, tonsils, Eustachian tube, and thymus and thyroid glands. It also forms the notochord; and the epithelial lining of the bladder and urethra.

CHARACTERISTIC	VOLUNTARY STRIATED	SMOOTH	CARDIAC.
Shape.	Long cylinder.	Spindle.	Stubby cylinder.
Length.	1-5 inches.	25-500 microns.	100-200 microns.
Nucleus.			
Number.	Many.	One.	One.
Location.	Peripheral.	Central.	Central.
Shape.	Intermediate.	Rod.	Oval.
Striations.	Cross and long.	(Longitudinal occasionally.)	Cross and long.
Sarcolemma.	Present.	None.	None.
Branches.	Occasional.	(Occasional.)	Always.
Arrangement.	In masses called muscles.	In layers.	As a syncytium.
Control.	By will.	Not by will.	Not by will.

—(Radasch's *Histology*.)

4. The trachea is lined by long columnar, ciliated, epithelial cells; these cells are often irregular in shape and rest upon a basement membrane.

5. The *patella* is a flat, triangular bone situated in front of the knee-joint; it is said to be a sesamoid bone developed in the tendon of the quadriceps extensor. Its anterior surface is convex and shows perforations for nutrient vessels; it is separated from the skin by a bursa. Its posterior surface is smooth and oval-shaped, and has two facets separated by a vertical ridge; these facets articulate with the two condyles of the femur. The superior border gives attachment to the rectus and crureus; the lateral borders give attachment to the vastus externus and vastus internus. The apex gives attachment to the ligamentum patellæ. The anterior surface is covered by the tendon of the quadriceps extensor, which is continuous below with the ligamentum patellæ.

It serves to protect the front of the knee-joint, and it increases the leverage of the quadriceps extensor muscle, by making it work at a greater angle.

6. THE SHOULDER-JOINT "is an enarthrodial joint formed above by the glenoid cavity of the scapula and below by the head of the humerus. Its ligaments are—glenoid, coraco-humeral, and capsular. The *glenoid* surrounds the edge, deepens the glenoid cavity, and is continuous above with the long head of the biceps tendon. The *capsular ligament*, extensive and loose, arises above it from circumference of glenoid cavity behind the ligament, is attached below to the anatomical neck of humerus, and is pierced by tendons of two or three muscles. The *coraco-humeral*, or *accessory*, is a fibrous band which extends obliquely downward and outward from the coracoid process to the anterior part of great tuberosity, strengthening the capsular ligament."—(Young's *Anatomy*.)

7. The *muscles which participate in tranquil respiration* are: The diaphragm, intercostals, levatores costarum and the scaleni.

8. The *blood-supply of the stomach:* gastric (or coronary), pyloric, right and left gastro-epiploic, and vasa brevia.

9. TRIFACIAL NERVE. *Origin:* (1) *Superficial*, from the side of the pons Varolii; (2) *Deep* (sensory root), from the medulla, and upper part of cord; (motor root) from floor of fourth ventricle, and side of the aqueduct of Sylvius.

Distribution: First, ophthalmic branch supplies sensation to conjunctiva and skin of upper eyelid, cornea, skin of forehead and nose, lachrymal glands, mucous membrane of nose. *Second, or superior maxillary branch*, supplies sensation to skin and conjunctiva of lower lid, nose, cheek, upper lip, upper teeth and alveolar processes, and palate. *Third, or inferior maxillary branch*, supplies sensation to external auditory meatus, side of head, mucous membrane of mouth, anterior two-thirds of tongue, lower teeth, lower lip and skin of the lower part of the face. This branch, in addition, supplies motion to the muscles of mastication (masseter, temporal, external pterygoid, internal pterygoid), also mylohyoid and anterior belly of digastric.

10. The dorsum of the tongue, at rest, is arched from before backward. On it is a median longitudinal raphé, terminating behind in the foramen cæcum. The anterior or oral part of the dorsum of the tongue forms about two-thirds of the whole, and is rough and covered with papillæ; the posterior third is smooth and contains muciparous glands and lymphoid follicles.

PHYSIOLOGY.

1. LYMPH. *Origin:* There are two theories as to the formation of lymph: (1) That it is formed from the blood plasma by the processes of filtration, diffusion, and osmosis. (2) That in addition to these, the endothelial cells of the capillaries exercise some influence. *Description:* Lymph is a colorless, albuminous fluid, alkaline in reaction, with specific gravity of about 1015, containing lymph corpuscles, and coagulating when drawn from its vessels. *Composition:* Proteins (serum albumin, fibrinogen), sugar, sodium chloride and carbonate, water, urea, fat. *Function:* To provide cells and tissues with materials necessary for their growth, repair, and functional activities; and to receive and carry away their waste products.

2. The *circulation of the blood* is the course or circuit of the blood from the heart, through the body, and back to the heart. Beginning at the left ventricle of the heart, the blood flows through the left semilunar valve into the aorta, from which branches are distributed to every part of the body, through the capillaries to the veins, from the veins to the venæ cavæ, thence to the right auricle of the heart. From the right auricle, through the tricuspid valve to the right ventricle, thence through the right semilunar valve to the pulmonary artery to the lungs, from the capillaries in the lungs to the pulmonary veins, thence to the left auricle, and through the mitral valve to the left ventricle, to begin the circuit again.

3. The object of the circulation is to convey arterial blood and products of digestion to all the tissues of the body, and to carry waste products from the tissues to various organs of excretion. As the blood passes through the body it gets warmed, until it reaches the lungs, where it is cooled. As the blood passes through the lungs the reduced hemoglobin of the venous blood becomes almost wholly, by the absorption of O, converted into oxy-hemoglobin.

4. In the *mouth*, the food is masticated, and mixed with saliva; salty substances and sugar may be dissolved, boiled starches are converted into maltose by the action of the ptyalin. In the stomach the food is mixed with gastric juice, more thoroughly triturated, moved around the stomach, and finally expelled into the duodenum. In the stomach the proteins are split up into proteoses and peptones by the pepsin of the gastric juice, and certain bacteria are killed by the hydrochloric acid; starches are not affected; fats are split up by a gastric lipase.

5. Respiration means the taking in of oxygen and the elimination of carbon dioxide. The respiratory act consists of inspiration and expiration. The origin of the impulses is at the respiratory center in the medulla. The phrenics and intercostals are the chief nerves conveying the impulses; and they are distributed to the diaphragm and intercostal muscles, respectively. External respiration is the interchange that takes place between the blood and the gases in the lungs; internal

respiration is the interchange that takes place between the blood and the tissues of the body. Respiration causes changes in the air as follows:

	EXPIRED AIR.	INSPIRED AIR.
Oxygen	16.6 per cent.	21 per cent.
Nitrogen	79 per cent.	79 per cent.
Carbon dioxide	4.4 per cent.	0.04 per cent.
Other gases	Often present	Rare.
Watery vapor	Saturated.	Variable.
Temperature	That of body.	Variable.
Volume	Diminished.	Varies.
Bacteria	None.	Always present
Dust	None.	Always present

6. *Enzymes* are bodies produced by living cells, and are capable of producing certain definite chemical changes in certain substances under certain well-defined conditions, and without themselves undergoing any alteration. Their chemical composition is unknown; not one of them has ever been isolated in an absolutely pure condition; it has been assumed that they are of a protein nature.

7. In the intestine, the food passed on from the stomach is mixed with the bile, pancreatic juice, and intestinal juice. Starches are converted into sugar by the amylopsin of the pancreatic juice; fats are emulsified and saponified by the action of the bile and of the steapsin of the pancreatic juice; proteids are split up into proteoses and peptones by the trypsin of the pancreatic juice and the erepsin of the succus entericus.

8.

EXCRETORY ORGANS.	EXCRETION.
Kidneys.	Urine.
Liver.	Bile.
Skin.	Sweat.
Lungs.	Carbon dioxide.

9. The *ductless* glands are: The spleen, thymus, thyroid, parathyroids, supraenals, carotid, coccygeal, pituitary, and pineal glands.

The function of the spleen: The following theories have been held: (1) It is a source of production of the white blood corpuscles; (2) it is a source of production of the red blood corpuscles during fetal life; (3) it is a place where the red blood corpuscles are destroyed; (4) uric acid is produced in the spleen; (5) an enzyme is produced in the spleen and is carried by the blood to the pancreas, where it converts the trypsinogen into trypsin.

The function of the thyroid is not definitely settled: (1) it has some trophic function, regulating oxidation in the body, and it is supposed to have also a special influence on the vasomotor nerves, the skin, the bones, and on the sexual functions; (2) it is supposed to antagonize toxic substances, and (3) it produces an internal secretion.

The *function of the thymus* is not settled; it is said: (1) To be a blood-forming organ; (2) to have influence on growth and nutrition; (3) in hibernating animals it is supposed to store up materials which can be utilized during the period of inactivity.

The *function of the suprarenals* is not definitely settled; they produce an internal secretion which is probably necessary to life; it is supposed that they are able to destroy or remove some toxic substance produced elsewhere in the body.

The function of the *other* ductless glands is unknown. They all, or nearly all, furnish an internal secretion.

10. The normal body temperature is *regulated* and *maintained* by the thermotactic centers in the brain and cord keeping an equilibrium between the heat gained or produced in the body and the heat lost.

Heat is produced in the body by: (1) Muscular action; (2) the action of the glands, chiefly of the liver; (3) the food and drink ingested; (4) the brain; (5) the heart; and (6) the thermogenetic centers in the brain, pons, medulla, and spinal cord.

Heat is given off from the body by: (1) The skin, through evaporation, radiation, and conduction; (2) the expired air; (3) the excretions—urine and feces.

CHEMISTRY.

1. A knowledge of chemistry is of the utmost use to a physician. It is essential to an understanding of physiology, toxicology, and materia medica; it is of use in diagnosis and prescription writing. Without it, any understanding of some of the vital processes going on in the body is impossible; and many tests are based on a knowledge of chemistry.

2.—

ELEMENT.	VALENCE.	ATOMIC WEIGHT
Hydrogen	1	1
Oxygen	2	16
Nitrogen	3 or 5	14
Carbon	4	12
Phosphorus	3 or 5	31
Chlorine	1	35.5
Potassium	1	39
Sodium	1	23
Calcium	2	40
Sulphur	2 or 6	32

3. (*a*) $MgSO_4, 7H_2O$ is magnesium sulphate, also called Epsom salt; it is a crystalline, white solid, slightly effervescent, soluble in water, and on being heated fuses and loses its water; it is used as a cathartic.

(*b*) $Na_2CO_3\ 10H_2O$ is disodic carbonate, also called washing soda; it is a white crystalline solid, and is soluble in water and effloresces on exposure to the air; it is used as a cleansing agent in washing.

(*c*) $CHCl_3$ is a trichlormethane, also called chloroform; it is a colorless, volatile liquid, with a sweet taste and a strong, characteristic odor; it is used as a general anesthetic.

(*d*) C_2H_2 is ethine, also called acetylene; it is a colorless gas, with a disagreeable odor, somewhat soluble in water, and forms an explosive mixture with air; it is used for illumination.

(*e*) H_3BO_3 is boric acid, also called orthoboric acid; it is a white, crystalline solid, sticky, soluble in water; it is used as a mild disinfectant.

4. (*a*) *Sal ammoniac* is ammonium chloride, NH_4Cl; it is an elastic solid, salty in taste, volatile, and soluble in water; it is used as a rapid stimulant.

(*b*) Saleratus is monopotassic carbonate, $KHCO_3$; it is a crystalline solid; it is used in baking powders.

(*c*) *Calomel* is mercurous chloride, Hg_2Cl_2; it is an amorphous powder, white or yellowish, insoluble in cold water; it is used as a cathartic.

(*d*) *Corrosive sublimate* is mercuric chloride, $HgCl_2$; it is a crystalline solid, and is soluble in water; it is used as a disinfectant.

(*e*) *Lunar caustic* is silver nitrate, $AgNO_3$; it is a crystalline solid, soluble in water; it is used as a caustic.

5. Glycerin is a triatomic alcohol, $CH_2OH.\ CHOH.\ CH_2OH$. It is obtained as a by-product in the manufacture of soaps.

$$\left.\begin{matrix}(C_3H_5)'''\\(C_{18}H_{35}O)'_3\end{matrix}\right\}O_3 + 3\left\{\begin{matrix}K\\H\end{matrix}\right\}O = \left.\begin{matrix}(C_3H_5)'''\\H_3\end{matrix}\right\}O_3 + 3\left\{\begin{matrix}(C_{18}H_{35}O)\\K\end{matrix}\right\}O$$

Tristearin, Potassium hydroxide, Glycerin, Potassium stearate.

6. The hardness of water depends on the presence of calcium salts, chiefly the bicarbonate and sulphate; if due to the bicarbonate the water should be boiled, when the calcium salt is decomposed and deposited.

7. The cloud or precipitate may be due to urates or phosphates. If it is due to phosphates, it will clear upon the addition of a few drops of nitric acid; if it is due to urates, it will disappear on being heated.

8. *Fehling's test:* Place in a test tube a few c.c. of the liquid prepared as stated below, and boil; no reddish tinge should be observable, even after five minutes' repose. Add the liquid under examination gradually, and boil after each addition. In the presence of sugar a yellow or red precipitate is formed. In the presence of *traces* of glucose, only a small amount of precipitate is produced, which adheres to the glass, and is best seen when the blue liquid is poured out.

[The reagent must be kept in two solutions, which are to be mixed immediately before use. Solution I consists of 34.653 gms. of crystallized $CuSO_4$, dissolved in water to 500 c.c.; and solution II of 130 gms. of Rochelle salt dissolved to 500 c.c. in NaHO solution of sp. gr. 1.12. When required for use equal volumes of the two solutions are mixed, and the mixture diluted with four volumes of water.]

Fehling's solution is also reduced by uric acid, creatinin, bile pigment, and certain drugs.

9. Copper in canned vegetables can be detected by inserting a large needle into the vegetable; if copper is present the needle will be found to be coated with copper in about half an hour.

10. In this prescription the strychnine would be pre-

cipitated by the ammonium salts, and the patient would get most of the strychnine in the last dose.

BACTERIOLOGY.

1. *Virulence of bacteria* may be increased by successive animal inoculation, by the addition of animal fluids to the culture media, by enclosing cultures of the bacteria in collodion sacs and placing the latter in the abdominal cavity of animals, and sometimes by increasing the temperature at which the bacilli are usually grown.

2. The *colon bacillus* may produce cholecystitis, cholangitis, gallstones, cystitis, lesions of the urinary tract, suppuration, and diarrhea; it has also been credited with causing peritonitis, appendicitis, enteritis, endocarditis, and pleurisy.

3. *Tuberculin* is a preparation made from cultures of the tubercle bacillus in glycerin broth; it is used for the diagnosis and (sometimes) treatment of tuberculosis.

4. The *bacterial findings in puerperal septicemia* include the *Streptococcus pyogenes*, *Staphylococcus pyogenes*, gonococcus, *Bacillus coli communis*, *Bacillus diphtheriæ*, *Bacillus aërogenes capsulatus*, and *Bacillus typhosus*.

5. Tetanus is caused by the *Bacillus tetani*, which "gains entrance to the body through wounds and abrasions, and, multiplying locally, produces poisons which diffuse into the tissues and have an elective action as stimulators, especially of the spinal cord. The chemical composition of these poisons is not yet fully known" (Muir and Ritchie). Tetanus antitoxin is administered with the view of its neutralizing the action of the tetanus toxin; its action is similar to that of diphtheria antitoxin. It only affects the toxins which are in the circulation, and its curative value is much lower than its prophylactic value.

PATHOLOGY.

1. *Death following burns may be due to:* Shock, exhaustion, duodenal ulcer, or from absorption of some toxic substance.

2. *Thrombosis* is coagulation of the blood within the vessels, during life. The endothelium lining the vessel wall becomes impaired, then roughened; fibrin ferment is liberated from the blood; the lumen of the vessel is narrowed; the blood-flow is diminished; the leucocytes tend to adhere to the vessel wall and fibrin is deposited. *Emboli are most frequently found* in the spleen, kidneys, and brain.

Emboli may consist of: Detached thrombi or fragments of thrombus; vegetations detached from the heart; foreign bodies such as air, bone, fat, oil, or parasites; calcareous plaques.

3. In *chronic alcoholism*, there may be found: sclerotic arteries; cirrhotic liver; enlarged heart, which may also be fatty; inflamed gastrointestinal tract; and nephritis.

4. *Isehemic paralysis* is paralysis of a part due to stoppage of the circulation—such as paralysis of the lower limb following embolism or thrombosis of the femoral artery.

5. *Stenosis of the tricuspid valve of the heart* is generally found in connection with mitral stenosis; it is apt to be accompanied by dyspnea; and edema, albuminuria, cyanosis, and enlarged liver are generally present.

6. *Carcinoma of the stomach* is usually primary, and is generally found on the lesser curvature and pylorus; the most common type is the cylindrical-celled epithelioma.

7. *Dropsical effusions in the abdomen and lower extremities may be caused by:* Cardiac dropsy; hepatic cirrhosis; pressure on the inferior vena cava by abdominal tumors, enlarged liver, spleen, pancreas, or mesenteric glands; chronic malarial poisoning with enlarged liver and spleen; thrombosis of femoral vein, or pressure on the femoral vein by tumor of groin or abdomen; lymphedema.—(From Butler's *Diagnostics of Internal Medicine.*)

8. *Diseases of the mother which may be transmitted to the fetus:* syphilis, smallpox, tuberculosis, varicella, measles, scarlet fever, erysipelas, rheumatism, cholera, typhoid fever, yellow fever, malaria, and influenza.

9. "*Caries* is a term applied to the molecular destruction of bone, corresponding to ulceration of the soft parts. It may be associated with osteomyelitis, or with necrosis due to traumatism or various infective conditions. The changes consist in progressive softening and crumbling of the bone, with eventual destruction of more or less considerable areas. Caries is especially frequent as a part of tuberculosis of the bones.

"*Necrosis* is a term applied to the death of a small or large portion of bone in mass. Necrosis may be partial or total, and may occur in the center of the bone or at the periphery. The dead portion of the bone, termed sequestrum, presents itself as an irregular, more or less eroded, fragment, almost completely or completely separated from the remaining structure. The separation occurs by the process of demarcation, as in necrosis of the soft parts. This line consists of an area of absorption of the calcareous matter and proliferation of the cellular elements. The necrotic portion, or sequestrum, acts as a foreign body, and by its continued irritation keeps up a suppurative inflammation of the surrounding tissues. Fistulous communication with the exterior is usually observed. If the sequestrum is peripheral and has been discharged, the periosteum or the bone may replace the lost tissue by regeneration. If the fragment is large or centrally placed, discharge is impossible and suppurative inflammation continues, sometimes for years. In these cases considerable hyperplastic material may be deposited over and around the sequestrum, and thus irregular thickening of the bone may be produced."—(Stengel's *Pathology.*)

10. *Malignant tumors* are not encapsulated, tend to infiltrate the surrounding tissues, give rise to metastatic growths, have a tendency to recur after removal, give a cachexia, have a fatal tendency.

Benign tumors are encapsulated, do not tend to infiltrate the surrounding tissues, do not give rise to metastatic growths, do not tend to recur after removal, do not produce cachexia, and do not have a fatal tendency (except from their location).

(To be continued.)

Case of Myasthenia Gravis, with Affection of the Larynx and Soft Palate.—E. D. Davis reports the case of a woman aged 25, who was admitted to Charing Cross Hospital in February last for Raynaud's disease. she complained, among other symptoms, of loss of voice, difficulty in swallowing, and regurgitation of fluids through the nose. Th loss of voice occurred suddenly, without apparent cause, in September, 1912, and was followed a little later by difficulty in swallowing and regurgitation through the nose. When seen in February, 1913, a diagnosis of functional aphonia was made, and in spite of the nasal voice and regurgitation through the nose no paresis of the soft palate was detected. Treatment by the faradic current, cold douching, valerian, etc., had no effect. At a second examination in June the condition had progressed, the paresis of the soft palate was well marked, the vocal cords abducted slightly, but remained in the cadaveric position during deep inspiration, and on vocalization very little abduction was produced. The pharynx and palate were somewhat insensitive. Organic nervous disease was now suggested, but no definite diagnosis was made. The Wassermann reaction was negative. The condition of the skin was also first noticed then. It was observed on repeated examinations that the amount of paresis varied and appeared to increase when examination was prolonged. On December 16 Gordon Holmes saw the patient for the first time and made the diagnosis of myasthenia gravis. This diagnosis was based on: (1) the muscular weakness and rapid fatigue; (2) the variability of the paresis; (3) the increase of paresis on exertion and the difficulty of mastication and swallowing; and (4) the affection of the cranial nerves —*Proceedings of the Royal Society of Medicine.*

Preadolescent Dyspituitarism.—F. G. Crookshank reports the case of a male aged 13½ years, weighing 151 pounds. He appeared to be in good health generally, but it was said that it was only in the last six months that he had become so fat. His father was over 6 feet in height, and the mother who was dead was said to have been a very stout woman. The boy had a definite limitation of the temporal half of the right visual field. Sugar tolerance had not yet been estimated. The boy was obviously very stout, but the distribution of the fat was feminine, and the external genitals were small. Associated with these characters there would seem to be some skeletal overgrowth. The size of the pelvis was notable. On the whole the case appeared to correspond to the type described by Cushing as differing from Frohlich's dystrophia adiposogenitalis in the skeletal overgrowth and in the markedly feminine distribution of the fat.—*Proceedings of the Royal Society of Medicine.*

Therapeutic Hints.

The "Triple-Acid" Ointment for Pruritus.—Brocq recommends the following as effective in the treatment of pruritus:

℞ Phenol, 1 gram.
Salicylic acid, 2 grams.
Tartaric acid, 3 grams.
Glycerite of starch, 80 grams.

A Simple Method for the Intravenous Injection of Neosalvarsan.—M. P. Le Damany describes a modification of Ravaut's simple technique for the intravenous injection of neosalvarsan. The virtue of the latter method consists in the small volume of solution used, which may be 10 cubic centimeters or even less. In order to avoid displacement of the needle in the vein while the piston is pushed home, the author interposes a piece of red rubber tubing having a lumen of 1 millimeter and a thickness of wall of 1 millimeter, between the syringe and the needle. This tubing is provided at each end with a metallic couple, the syringe end being female and the needle end being male. The syringe should be all glass. The neosalvarsan is dissolved in sterilized distilled water, and is then drawn up into the syringe through a piece of sterile rubber tubing which contains in its lumen a bit of absorbent cotton which acts as a filter. The syringe and the special tubing described above are then held vertically and all air is expelled from the apparatus. A tourniquet is applied to the patient's arm above the elbow, and the skin in the region of the bend of the elbow is cleansed with alcohol. The needle is plunged into the median basilic vein and the blood is allowed to run freely until one is certain that the needle is in the vein. The tubing is then attached to the needle. It is not necessary to hold the latter for the constriction of the tissues that it has traversed suffices to keep it firmly in place. The solution is injected slowly. If any of it enters the subcutaneous tissue, this fact is at once made evident by an area of edema in the region of the puncture.—*La Presse Médicale.*

Lactucarium in the Treatment of Opium Smokers.—Millan has found that this drug provides an effective substitute for opium in the treatment of those addicted to opium smoking. The extract of lactucarium is softened in the water-bath to a syrupy consistency and is then rolled into pills similar to the pills of opium used by smokers of this drug. When smoked in the pipe lactucarium produces a sedative effect similar to that produced by morphine. The preparations of lactucarium usually contain a minute percentage of morphine. This is no disadvantage in the treatment for the author does not break off the opium abruptly, but uses a slight admixture of it with the lactucarium, diminishing the amount, however, from day to day. —*Le Caducée.*

Diphtheria Antitoxin in the Treatment of Pneumonia.—J. L. Elizagaray has essayed the application in pneumonia of this form of therapy, which a number of years ago was tried in other diseases, notably in meningitis. The theory upon which this treatment is based is that the antibodies contained in the diphtheria antitoxin may be effective against toxins other than those of the diphtheria bacillus. The author finds that in mild and moderately severe cases of pneumonia the diphtheria antitoxin hastens convalescence, but that it has no effect in diminishing the mortality in severe cases of this disease.—*Revista Clinica de Madrid.*

THE LOW TABLE POSITION AND OTHER AIDS TO PERFORMING SUPRAPUBIC PROSTATECTOMY.*

BY C. L. GIBSON, M.D.,

NEW YORK.

From the First Surgical (Cornell Medical) Division of the New York Hospital.

IN common with many operators I have abandoned the perineal prostatectomy which I practised almost exclusively for ten years to return to the suprapubic operation which I had used fifteen years ago. The earlier suprapubic operations gave me a much larger mortality than the subsequent perineal operations, and there is no doubt in my mind that there is distinctly less shock, generally speaking, in the lower route. The various modifications and improvements of the modern suprapubic operation have, however, made it nearly as safe and the operation gives much better final results.

The operation as I do it now is simple, time-saving and is distinctly less risky than when I began my prostatic work. It has four features which I think are all important in attaining these better results—the special position, the anesthetic, rapidity of operating, and more efficient after treatment by improvement in the method of drainage.

Position.—This particular feature gives me a pretext for writing this paper and giving it its title, "The Low Position."

Instead of using the Trendelenburg position, I not only have the patient in the horizontal position, but also use a special table 24 to 26 inches high. The advantage of such a position was revealed accidently. I opened a patient's bladder in his bed under nitrous oxide anesthesia to drain a bladder filled with clots. To my examining finger the prostate seemed so easily accessible that almost involuntarily I enucleated it in a few seconds' time, the very elderly patient making a prompt recovery. On analyzing the features of the operation I became convinced that this unexpected ease was no accident, but due to a mechanical advantage not existing usually, the ordinary bed requiring a stooping position. By this low position one brings in leaning downward the weight of part of the operator's body on the abdominal wall which being so totally depressed also allows of the easy working of the enucleating fingers in the bladder without loss of force. Fig. 1.

Anesthetic.—It is, however, in combination with the anesthetic of choice—nitrous oxide and oxygen—that the greatest advantage of this overcoming of the muscular resistance becomes manifest. The anesthetic does not have to be pushed to get complete relaxation—sometimes impossible to get without ether or chloroform.

"Gas oxygen," therefore, under these circumstances is, I believe, the best anesthetic of all. Ether or chloroform I bar absolutely, certainly for the "bad risks," and spinal anesthesia presents no advantages over gas oxygen and has distinct psychic drawbacks. The effectiveness of the gas oxygen is much increased by giving a hypodermic of morphine, one-fourth or one-third of a grain, about an hour before operation.

Operation.—The operation is performed as follows: The patient is placed on the low table. In most cases by omitting one or two scheduled catheterizations, the bladder is sufficiently distended. Any necessary distention (and not much is necessary) must be done by injecting water, *as air distention is unquestionably fatal at times.* The laughing gas and oxygen anesthesia is administered by an expert. The skin is painted with one coat *fresh* Tr. iodine. A mid line incision three to four inches long is carried down to the recti muscles which are separated by blunt dissection. Retractors expose the distended bladder. At its upper portion a suture is introduced on either side through the prevesical fat and the whole thickness of the bladder wall (no stripping back of fat or peritoneum, *i.e.* mangling of the tissues). The bladder is opened between these traction sutures of chromic catgut. An opening admitting two fingers snugly is sufficient. Bladder palpated, stones removed if present.

The enucleation is easily accomplished by following Squier's procedure, introducing the index finger into the urethral opening and penetrating into and through the thin layer of prostatic tissue overlying the urethra. Having arrived at the outer surface of the prostate it is easily shelled out of its capsule piecemeal, sometimes whole. When one has distinctly struck the line of cleavage the procedure is most rapid and the bleeding is slight. Care must be taken that no pedunculated bits of prostatic tissue or strips of mucous membrane are left to fall into the vesical outlet to act as a ball valve obstruction. A rubber tube about eight inches long, interior caliber one inch, is inserted just clear of the floor of the bladder. The original traction sutures are now tied and they will sufficiently close the opening around the big tube to make much more suturing generally unnecessary. While the abdominal wall is being closed the "sucker" has been introduced into the bladder through the short, wide drainage tube. It is not discontinued till the patient is actually removed from the operating table.

The patient is now transferred with all possible dispatch to his bed where a similar apparatus should be coupled up in readiness to be introduced into the drainage tube so soon as the patient returns to

*Read before the meeting of the American Association of Genito-Urinary Surgeons at Stockbridge, Massachusetts, May, 1914.

bed. If this procedure has been properly carried out the after care will present a minimum of trouble. The bladder is kept at all times free from blood

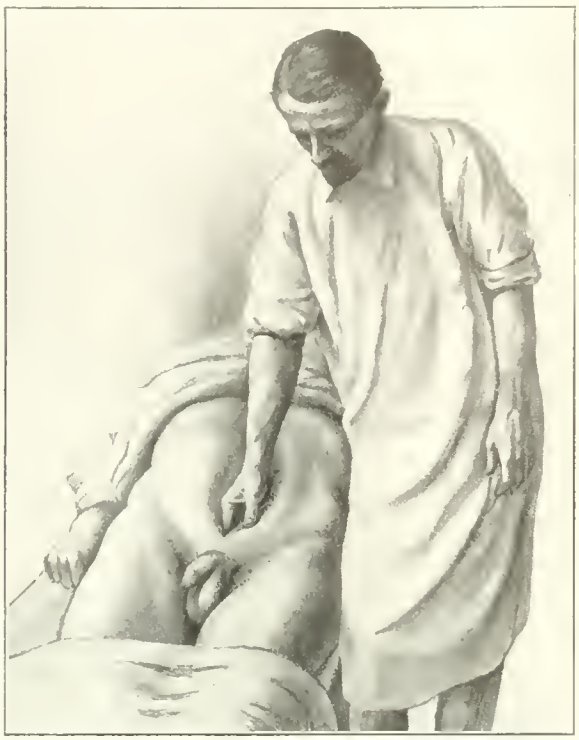

FIG. 1.—The operator leans on the patient, depressing the abdominal wall and overcoming the imperfect relaxation entailed by the gas-oxygen anesthesia.

and the annoyance of clot formation. In forty-eight hours any notable oozing will have ceased, the

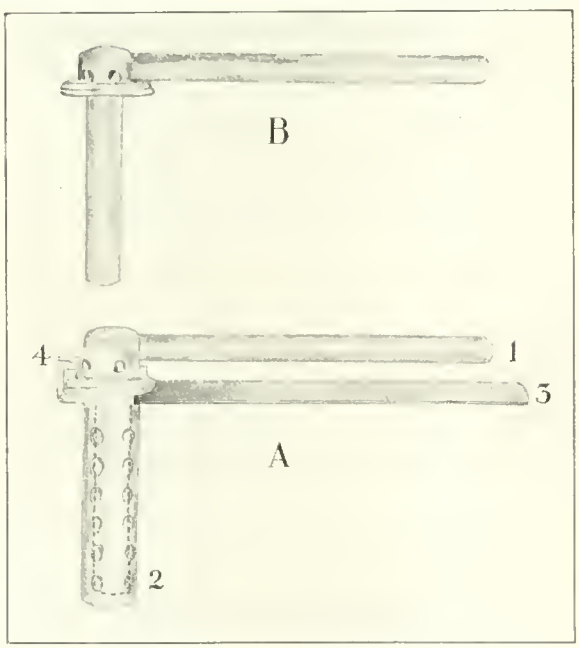

FIG. 2.—A. Double metal tube for continuous suction in postoperative treatment. 1. Inner tube with corrugated tapering end to be connected with rubber tube from the suction bottle. 2. Short fenestrated outer tube with rounded end to be inserted in the wound. Dotted line shows the position of inner tube. 3. Thin strip of malleable metal, continuous with outer tube, which can be bent to fit the surface of the body. It is held in place upon the skin with strips of adhesive plaster. 4. Hooklike projection on outer tube overhanging flange on inner tube holding the two together. B Inner tube removed showing flange with notch which fits under the hook shown in A. 4.

large tube will have outlived its usefulness and may be removed, suction still being kept up by attaching a small-sized catheter to the "sucking" apparatus. This catheter is introduced a short way into the vesical lumen.

After-Care.—The patient should be made to drink large amounts of water. If the intake does not seem sufficient or the patient shows any untoward manifestations such as shock or uremia, continuous instillation of water in the rectum by the Murphy drip will bring great improvement in his condition. The patient should have suitable nourishment in generous quantities, should be propped up in bed and frequently urged to change his position. Within a week, sometimes less, the patient may be allowed out of bed for portions of the day. Meanwhile, the sucker apparatus, after its final withdrawal from the bladder, say in eight or ten days, is applied at the later stages to the surface of the wound, thus keeping the patient perfectly dry.

The suction apparatus which contributes so much to the patient's comfortable and successful convalescence is the one devised by Kenyon and Pool. (*Surgery, Gynecology and Obstetrics*, December, 1909.) They say, "To produce the required suction . . . simplest and most practical device is one in which the suction is produced by water or steam on the principle of the Sprengel pump. A serviceable apparatus of this type is the H. D. ejector made by Hayden & Derby Co. This model can be operated by water or steam at any pressure over 20 pounds, and may be connected with a water or steam pipe whenever convenient."

Fig. 2 shows some tubes for suprapubic drainage to be used in connection with the suction apparatus. They have also been devised by Kenyon, who has kindly furnished me with the drawings.

COCCYGODYNIA — A NEW METHOD OF TREATMENT BY INJECTIONS OF ALCOHOL.*

BY FRANK C. YEOMANS, A.B., M.D.,

NEW YORK.

INSTRUCTOR IN SURGERY, COLLEGE OF PHYSICIANS AND SURGEONS (COLUMBIA UNIVERSITY); ADJUNCT PROFESSOR OF RECTAL DISEASES, NEW YORK POLYCLINIC; SURGEON TO THE CENTRAL AND NEUROLOGICAL HOSPITAL, THE WORKHOUSE AND THE PENITENTIARY HOSPITALS.

J. C. NOTT reported a case of "Extirpation of the Os Coccygis for Neuralgia" in a woman, aged 25, in the *New Orleans Medical Journal* of May, 1844. The two distal segments of the coccyx were removed, the terminal one being carious, and a cure resulted. This, I believe, is the first instance of record in which the bone was resected for pain.

Sir J. Y. Simpson, of Edinburgh, however, was the first to describe the condition as a definite entity to which he gave the name coccyodynia (κόκκυξ coccyx, + ὀδύνη pain), and to report a number of cases, in an able lecture on "Coccyodynia and Diseases and Deformities of the Coccyx," published in the *Medical Times and Gazette* of July 2, 1859.

Strictly speaking, the affection is neurological, but in practice it has been considered by some as medical and by others as surgical. Thus, being a border-line condition, it has received scant mention in the text-books, but because of the serious symptoms to which it gives rise it may well engage our earnest attention. The leading symptom is pain

*Read at the sixteenth annual session of the American Proctologic Society, Atlantic City, June 22-23, 1914.

in the region of the coccyx. The earlier writers, notably Simpson, thought that the pain was due to traction on the coccyx by the attached muscles and ligaments. More recently several theories have been advanced as to the etiology of the pain:

Fig. 1.—Bidigital examination to determine point of maximum tenderness.

1. The *neuralgic* theory, advocated by Marro, Pozzi, and others, claims that there is no definite anatomical lesion, but that the initial trauma caused violent nerve irritation which persists without any anatomical changes.

2. Gräfe holds it to be a *neuritis* and so explains twelve cases in women as due to pressure of the fetal head on the terminals of the sacral plexus. This accounts for those cases only that follow labor.

3. Theory of *injury* of the coccyx, resulting in fracture, dislocation, ankylosis, or caries.

4. *Symptomatic*, *i.e.* a referred pain of central origin due to many functional or organic diseases of the nervous system. Starr mentions its frequent occurrence in neurasthenic and anemic persons, chiefly in women, and states that in the majority of cases it is a purely hysterical symptom. He also says that it may be associated with irritable spine and occur in cases of traumatic neurosis. Strümpell mentions its presence in two individuals with tabes dorsalis. Pain about the coccyx and anus is quite common in tabes but usually occurs at intervals.

Viewed broadly, then, all cases of coccygodynia may be classed as traumatic or symptomatic, *i.e.* dependent upon an organic change or functional disturbance of the central nervous system. In the traumatic cases the impact may be from within the pelvic canal or external. Difficult labor is the chief example of internal violence. Instances resulting from external force are by far the commonest and usually the patients give the history of a fall which may cause injury of the soft parts only or fracture, dislocation, ankylosis, or caries of the cocyx and result in neuralgia or neuritis of the coccygeal plexus of nerves. As a rule, no gross lesion of the coccyx is demonstrable. The injury usually affects the periosteum only and the soft structures adjacent or attached to the bone. Repeated traumata, as in horseback riding, have been responsible for some cases.

Symptomatically it may occur in toxemia, hysteria, neurasthenia, irritable spine, the traumatic neuroses, and tabes dorsalis, or may be even a "habit pain." Although practically limited to women, a few examples have been reported in men.

Anatomy.—A consideration of the anatomy of the coccygeal plexus of nerves and the relations of the latter to the sympathetic system will elucidate the protean disturbances of sensation occurring in coccygodynia. The nerves entering into the formation of the coccygeal plexus are the fourth and fifth sacral, except the visceral branch of the fourth anterior sacral; the coccygeus, anterior and posterior branches, and probably the inferior hemorrhoidal branch of the internal pubic.

Moreover, there are on the anterior surface of the coccyx two ganglia which belong to the pelvic system of the sympathetic. These coccygeal ganglia are united to each other by a small nerve filament and are connected by other filaments to the last sacral ganglion of the chain which constitutes the pelvic sympathetic. (Hamant and Pigache.)

Very naturally, then, irritation of any part of a nerve plexus so intimately related to the central and the sympathetic nervous systems may give rise to the most varied symptoms. Jointly the nerves supply sensation to the integument over the coccyx, around the anus and the intervening area, and innervate the levator ani, sphincter ani, and coccygeus muscles, all of which are attached to the os coccyx.

All of the cases I have seen and most of those reported give a history of injury, most frequently a fall, and I am forced to the conclusion that trauma is the causal factor in the greater number of cases of coccygodynia. The only exception may be certain symptomatic cases. Even here the history of injury should be very carefully investigated. Why a painful condition should follow such injury is evident. The coccyx is a small bone, but given insertion to the levator ani (in part) and coccygeus muscles on its anterior surface, the gluteus maximus (part of origin) on its posterior surface, while the sphincter ani is inserted into its tip. The sacrosciatic ligaments are also attached to it. Thus the coccyx is surrounded by dense structures, largely fibrous, which the delicate network of nerves penetrates.

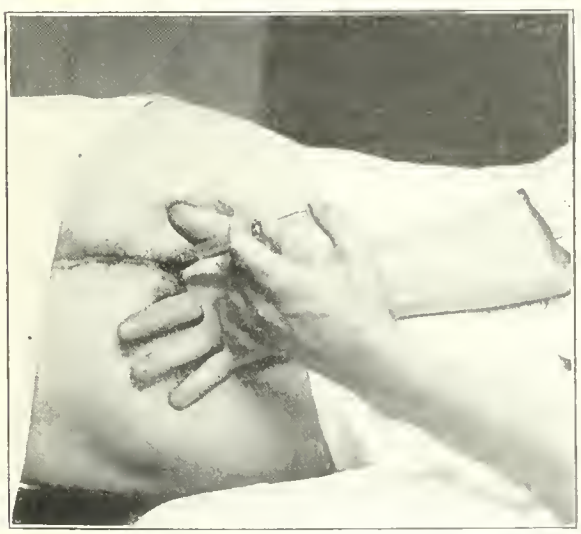

Fig. 2.—Making the injection.

If these structures are bruised an inflammatory reaction naturally results with proliferation and subsequent contraction of the new fibrous tissue and compression of the nerves.

Injury of the bone, as fracture or dislocation, in like manner causes pressure pain. Pressure upon the nerves either by the injured bone or by the contraction of the injured soft parts produces neuralgia. If the pressure is maintained, inflammation takes place in the nerves, *i.e.* neuritis results, or neuritis may occur at the beginning if the primary injury is of sufficient severity.

Symptoms.—The predominant symptom is a characteristic spasmodic, aching pain in the region of the coccyx, increased by sitting or rising, and at times by defecation and urination. Consequent avoidance of stool may result in constipation. While it may be a symptom of a hysterical condition, conversely, in the writer's opinion, coccygodynia long continued will result in a general neurotic state. The pain may be localized or radiate to the perineum or bladder.

Diagnosis.—This is established by a thorough examination, both general and local. The former embraces the spinal column to determine injuries or disease as caries, and the nervous system to exclude tabes dorsalis, hysteria, the neurosis, etc., as well as autotoxemia. The local external examination with the patient in the Sims' posture determines the position of the coccyx and the point of maximum tenderness which is usually just beyond its tip. The anal canal is then examined. An anal fissure may give all the symptoms characteristic of coccygodynia as also may cryptitis or inflammation of the crypts of Morgagni. A blind internal fistula, hypertrophied anal papillæ and foreign bodies in the rectum must also be excluded, as must rectitis by proctoscopy. The well lubricated index finger is next introduced into the rectum and the coccyx grasped between it and the thumb outside. The exact position, contour, mobility, and tenderness of the coccyx can thus be determined at once. If now the soft parts just distal to the tip of the coccyx are compressed between the examining fingers, the patient will complain of exquisite pain—the diseased coccygeal plexus of nerves has been squeezed and the pathognomonic symptom elicited. (Fig. 1.) In women a vaginal examination must also be made to determine the position and condition of the uterus and its adnexa, while in men the prostate, seminal vesicles, and urethra are examined for abnormalities which might cause reflex pains.

The *prognosis* hitherto has been more favorable in the traumatic cases than in those of frank neuralgia or neuritis without demonstrable associated lesions. However, with the treatment proposed, the writer confidently predicts that the latter will be equally amenable to treatment.

Treatment.—The methods of treatment that have yielded varying degrees of success are legion and only serve to emphasize their unreliability. They include local applications, counter irritation, electricity in its various forms, subcutaneous division of all muscles and ligaments attached to the sides and tip of the coccyx (Simpson) and finally excision or resection of the coccyx. Removal of the coccyx, wholly or in part, was based on the erroneous idea that the pain resided in the bone rather than in the nerves and has wisely been abandoned except in those rare cases where it is diseased or deformed. Relief seldom followed removal of the coccyx in other cases. In fact, the patient suffered a trying operation and was left in a rather worse condition from a weakened pelvic floor.

The treatment proposed by the writer is an application of the principle of injection of sensory nerves with 70 to 80 per cent. alcohol, thereby causing their degeneration, as suggested by Professor Schlösser* of Munich in 1907, and practised with marked success by him and his many followers, particularly in neuralgia of the trifacial nerve.

All of my cases were of the type of neuralgia or neuritis of the coccygeal nerves in which this method is peculiarly applicable, though I think it should be tried in all cases of coccygodynia, whatever their nature, as its application is simple and harmless. It may relieve the distressing pain even though it does not affect its cause.

The *technique* is easily carried out at the office under strict aseptic precautions. The patient, with rectum empty, assumes the left lateral (Sims') position on a firm table, with the thighs well flexed on the abdomen, and the region of the coccyx is painted with tincture of iodine. An all-glass Luer or similar sterile syringe of two centimeters capacity is filled with 80 per cent. alcohol and armed with a two-inch needle of fine gauge. The right index finger is now inserted into the rectum and the point of maximum tenderness is determined by counter pressure with thumb outside. In my cases this has been just below the tip of the coccyx in the midline or slightly lateral to it. Maintaining the finger in the rectum to guard against its puncture and to act as a guide, the needle is now introduced through the midline directly to the painful spot. (Fig. 2.) When this is reached the patient exclaims from pain that is exquisite but tolerable, and the injection of 10 to 20 minims is made slowly. The needle is withdrawn and its puncture sealed with collodion after neutralizing the iodine on the skin with alcohol. The pain from the injected alcohol lasts a few minutes only and may be followed by a dull ache for a day or two. It is conceivable but not probable that a single injection would work a cure in some cases. As a rule, three and at the most five injections should suffice. The interval between the injections should vary from five to ten days—one week on the average—and they are to be made always at the point which is found most tender at the time of injection. A consideration of the rather broad distribution of the coccygeal plexus of nerves already stated readily explains the necessity of repeated injections.

The writer's experience is limited to the seven cases here reported owing to the comparative rarity of the disease, but the outcome in these has been so favorable that he earnestly commends it to others for trial.

Case I.—Miss F., aged 29 years, developed Pott's disease in her seventh year. By wearing a plaster jacket cast she was cured when fourteen years of age, but has marked spinal deformity. She fell six months before I saw her, striking the coccyx. Since then she has had pain low down on right side of the back radiating to the hip, and "a feeling as if the spine were telescoping"—prevented her sleeping. Pain in the coccyx gradually increased, and was the predominating symptom when she was referred to me in June, 1910. Examination showed the coccyx deviating to the left and not movable laterally. Antero-posterior motion caused pain at the sacrococcygeal joint, and marked tenderness was elicited by compression of the soft parts between the tip of the coccyx and the anus. As all the routine measures had been tried, it occurred to me that injections of alcohol might be beneficial. On June 23, 1910, ♏ xv of 80 per cent. alcohol were injected by the method described above. June 30, pain relieved.

*Schlösser: "Erfahrungen in der Neuralgebehandlung mit Alkoholeinspritzungen." Proceedings of the Congress of Internal Medicine, Wiesbaden, 1907, XXIV, pp. 49-55.

Dull ache persists. Sleeps better. Injected ♏ xv. July 10, repeated injection. No further pain, but dull ache occasionally which disappeared in a fortnight and she has remained well since.

Case II.—Miss S., aged 36, fell, striking the lower part of her spine three months before I saw her in October, 1911. The pain disappeared except in the region of the coccyx. She could not sit, rise, or walk with comfort and had become very nervous. Examination showed a spare, neurasthenic woman, with normal genital organs. The coccyx was normal in position and mobility. The soft parts intervening between the coccyx and anus were very tender. After five injections of 10 to 20 minims each of 80 per cent. alcohol, given at intervals of one week, all pain disappeared and her general condition improved markedly. As she has not returned to my class at the Vanderbilt Clinic, I presume that she has remained well.

Case III.—Miss R., aged fourteen years, schoolgirl, came under my care January 11, 1913. Six months before she fell while roller-skating, striking the lower part of her spine. One month later she developed pain over the coccyx which is very severe when she sits or rises. Bowels move 3 or 4 times daily without pain. Frequent micturition. Urine normal except that indican is in excess. She has never menstruated. Appetite voracious. Examination shows a very stout, over-developed girl with normal organs. The coccyx is normal, but pressure just beyond its tip by the finger in the rectum elicits exquisite tenderness. Jan. 30, 1913, injected 80 per cent. alcohol ♏ x. Feb. 6, pain diminished. Repeated injection. Feb. 13, slight pain still present. Injected ♏ x. Feb. 20, pain absent till past three days. Repeated injection. May 16, 1914, fifteen months after the last treatment, she reported that the pain had been absent since the last injection and that she felt perfectly well. Examination elicited no tenderness.

Case IV.—M. S., widow, aged 42, came under my care at the Workhouse Hospital, June 7, 1913. She had had the diseases of childhood, but otherwise was always well till the birth of her third and last child seven years ago. Since then she had intractable pains in the region of the coccyx. For this all her internal organs of generation had been removed at three laparotomies. The perineum was also operated upon three times and the coccyx removed, but the pain still persisted. She complained of severe dragging pain at lower part of the sacrum and in the rectum. She also suffered from "nervous spells," in which she fainted and had convulsions. She drinks alcoholics to excess, as she expressed it "to drown her trouble." Physical examination showed a medium sized woman, fairly well nourished and of good intelligence. The chest and abdomen were normal. Perineum was lacerated. Area over the normal site of the coccyx was very sensitive, and when compressed between the finger in the rectum and thumb outside was exquisitely tender. Protoscopy was negative. June 7, 1913, injected 80 per cent. alcohol ♏ xx, in the sensitive area. June 17, pain diminished. Injected ♏ xx. Aug. 19, pain absent since last treatment. Considers herself cured.

Case V.—M. W., widow, aged 39. She had a miscarriage at 20 and was operated upon for appendicitis one year ago. Two years before admission to my service at the Workhouse Hospital in June, 1913, she fell, striking on the tip of her spine. Since then she had been unable to sit without pain which was aggravated by rising. Examination showed a markedly tender point just beyond the tip of the normal coccyx. June 13, 1913, injected 80 per cent. alcohol, ♏ xv. July 10, improved. Injected ♏ x. Aug. 19, still some pain. Injected ♏ xx. This gave permanent relief while she remained in the institution.

As Cases IV, and V, were inmates of the Workhouse, I am unable to give a later report.

Case VI.—E. G., aged 19, single, consulted me April 25, 1914. She had diphtheria in childhood, but no other illness and was strong and well nourished. Six years before visiting me she fell one story from a fire escape striking on her buttocks. Following this fall she had attacks of pain in the region of the coccyx, especially after standing or walking. Three months ago she sustained a second fall on the buttocks. Since then the pain had been markedly aggravated and was also present when she sat or attempted to rise. Her bowels were constipated, but the stools were painless. Local examination showed marked tenderness over the entire coccyx, especially at its tip. April 25, 1914, injected 80 per cent. alcohol ♏ viii, at the most tender point. May 4, less pain. Injected M vii, just to the left of tip of coccyx. May 9, very little pain or tenderness now. Injected ♏ x, at the right of tip of coccyx. June 10 reported freedom from pain.

Case VII.—M. B., a widow, aged 69 years, fell in December, 1912, striking upon her buttocks and the tip of the spine. Thereafter she suffered pain in the coccygeal region. This pain was aggravated by motion and was present even when reclining when she consulted me in April, 1914. At that time local examination showed the coccyx normal in position, not ankylosed but very tender, particularly along its margins and tip. April 20, 1914, injected 80 per cent. alcohol, ♏ vii, at the tip of the coccyx. April 25. Some improvement. Injected ♏ viii. May 9. Condition about the same. Injected ♏ x at the left margin of the coccyx. May 23. Markedly improved. Pain now only when sitting or rising. Injected ♏ xv just to the left of tip of coccyx. June 11. Reports feeling well since last treatment.

Recurrence has not taken place, to my knowledge, in any of my cases. The time that has elapsed since treatment has varied from four years to one month. This would seem to justify the expectation of permanent cure. However, should relapse occur, a repetition of the treatment is a simple matter.

230 West Fifty-ninth Street.

REPORT OF FOUR CASES OF WHAT APPEARED TO BE TUBERCULOUS MENINGITIS WITH APPARENT PERMANENT ARRESTMENT.*

By CHAS. C. BROWNING, M.D.,

Los Angeles, Cal.

Associate Professor of Medicine, University of Southern California.

Tuberculosis in any tissue may be acute, subacute, or chronic in its course. The terminal stage of tuberculosis may be infiltration, fibrosis, caseation, chalcosis, or complete breaking down and destruc-

Fig. 1—L. W., photograph taken July 18, 1909, when the child was 2 years 7 months old. Note evidence of emaciation.

*Read at meeting of American Climatological Association, Atlantic City, N. J., June 20, 1914.

tion of tissue, or a combination of two or more of these changes. It is always a replacement disease, the replacement remaining permanent.

These conditions must be considered in discussing the curability of tuberculosis of any tissue. If

Fig. 2—L. W., photograph taken 20 days later than Fig. 1. Note continuance of emaciation. Apparent slight flatness left side of face.

a return to the former condition of tissue is indicated by the term cure, such does not occur. If clinical restoration to health of the individual or restored function of an organ is the requisite, cures occur. Pathological cures may not occur. Clinical cures do occur. Tuberculous conditions tend toward arrestment. These may only amount to slight amelioration of symptoms, or to a distinct remission of greater or less extent which may terminate in a condition of arrestment, temporary or permanent. This tendency varies greatly in different tissues, that of the meninges being very slight.

Tuberculous meningitis is probably always secondary to active process in other tissues. The meningeal involvement may be general or localized, acute, subacute, or chronic. The gravity of the meningeal infection may be such that the primary focus may be quite overlooked or cease to be of importance from a prognostic standpoint.

It may accompany an attack of acute general miliary tuberculosis, in which the general condition is so grave that the final outcome may not be materially influenced by the meningitis, but the existence of meningeal involvement is always sufficient cause for grave prognosis. Sufficient numbers of cases, however, have been reported of prolonged arrestment of activity, or cures, to show that, while such termination is not frequent, it is possible.

George A. Crace-Calvert, London, reports four cases of recovery in the *Medical Press*, July 9, 1913. He quotes Martin, reported in *Brain*, Vol. XXXII., recording twenty undoubted cases of recovery since 1894.

Reichman and Rauch, abstract in the *Journal of the American Medical Association*, August 9, 1913, report two cases of recovery; one a child two years old, the other a robust young man. They collected eighteen other cases, more than half of which have been reported during the past five years.

Professor Rotch, in his work on Pediatrics, 1903, reports two cases of recurrent meningitis, stating these cases are rare, the disease being almost uniformly fatal in first attack. The first was that of a child, 21 months old, who died of subacute tuberculous meningitis, which gave a history of having suffered from symptoms of meningitis at intervals since nine months of age. Autopsy showed old tuberculous lesions in meninges, as well as those which produced the symptoms from which the patient died. This case showed tuberculous lesions in other organs both of a chronic and acute miliary character. A second case of Pott's disease developed symptoms of meningitis May 7, and continued 5 days, when it appeared well. Recurrence of symptoms for short periods followed by remissions for 25 days when remission of 2 months occurred, with symptoms for 2 days. Following this there were no symptoms for 10 weeks. Symptoms again recurred, followed by death in 4 days. The post-mortem showed recent tuberculous meningitis. In addition older large tubercles of brain and remains of previous attacks of tuberculous meningitis.

Fig. 3—Photograph showing the condition of patient L. W. Sept. 26, 48 days after first ocular symptoms were manifest. There had been improvement of general physical condition but steady progress of focal manifestations.

Professor Hutinol (*Presse Médicale*, November 15, 1912) suggests caution against mistaking a remission for recovery, and cites case of girl, 9 years of age who, in 1874, had tubercular meningitis producing hemiphlegia. She recovered from all symptoms only to die 25 years later of tuberculous meningitis. I think we would be justified in classifying this case as an arrestment.

The following cases have been reported:

Phipps Institute reports:		
3-8 years, inclusive	5	
9-20 years, inclusive	5	
21, over	4	
Total age limit stated	14	
Age not stated	18	
Total		32

Cases reported as undoubted cures (arrestments):		
Martin collected	20	
Crace-Calvert reported	4	
Reichman-Rauch reported	2	
Reichman-Rauch collected	18	
Total		44
		76
Following cases		4
Grand total		80

Some of these may be duplicated, but probably others which have been reported are not included. Even the most sanguine must conclude that recoveries are rare. These are sufficient to encourage me to report the following cases:

CASE I.—In July, 1885 (29 years ago) I was called to see A. R., near Carthage, Ill., age 4 years, whose parents had died of tuberculosis before she was one

FIG. 4—L. W., photograph one month later than Fig. 3. Note improved general condition. Less spasm of muscles of neck and back. Still pronounced ptosis, flatness of left side of face, limp condition of right hand and foot.

year of age, both having an active tuberculous condition before she was born, she having been cared for in a small house with them until their death. The patient had had, and still had at the time of the present illness, enlarged cervical lymphatic glands. The signs and symptoms were those of acute meningitis. The case ran the ordinary course of this disease for about 4 weeks, during which time three physicians saw her in consultation with me. All agreed that it was probably a case of tubercular meningitis. At the end of the fourth week the symptoms began gradually to subside, a tedious convalescence terminating in apparent recovery. After about a year the patient passed from my observation and was not seen again until 2 years ago when she moved to California from Illinois and came to my office. Her health was apparently good, she having had no return of former symptoms. At last account she was teaching school in one of the counties in the central part of the state.

FIG. 5—L. W., fifteen days later, improvement continues. Ptosis much improved, improvement less marked in left eye. Note storm on right side of face and calm on left

I am quite aware that this case lacks the scientific data which would be required at this time for diagnosis of tuberculous meningitis, and were it

FIG. 6—L. W., eleven days later. Continued improvement. Note healthy appearance of brothers—the other two children in the family.

not that other cases have been reported of which there could be no doubt of the nature of the illness, I should regard the diagnosis in this particular case as probably incorrect. I report it at this time, leaving persons interested to draw their own conclusions.

CASE II.—H. G., age 18, domestic, entered the County Hospital (via ambulance) May 12, 1912.

Family History.—One paternal and one maternal grandparent died of tuberculosis, otherwise history was negative.

FIG. 7—L. W., showing condition Jan. 6, 1910, eighteen days following onset of measles.

Past History.—Patient gave a history of poor health all her life. She had had all the children's diseases in severe form, also typhoid fever and pleurisy, the latter in 1911, six months previously. Menstrual periods began at 13, had always been scanty, irregular, and extremely painful. There was an indefinite history of "heart trouble" in 1911.

Present Illness.—Began 4 days before entrance to hospital when patient states she "became cold and stiff." For some time previous there had been some loss of weight, fever, cough and expectoration (mucopurulent), night sweats and shortness of breath. Patient complained of severe abdominal pains, loss of appetite and obstinate constipation.

Physical Examination.—Of the chest revealed evidence of active pulmonary tuberculosis in both upper lobes. Temperature irregular, 97°-101°, frequently from 98°-99.5°; pulse 70-100. Heart sounds weak and irregular, mitral regurgitant murmur.

Vaginal Examination gave extreme tenderness and mass on right side.

Laboratory Examination.—Urine was negative. Sputum showed slight mixed infection. No tubercle bacilli. Cutaneous test actively positive.

Operation on June 7, 1912, 26 days after entering hospital, which consisted of an appendectomy, plastic work on both ovaries, and a curettage.

The clinical-pathological report was as follows: Sclerotic condition of ovaries and endometritis—evidence of tuberculosis in appendix and ovaries.

About the middle of July patient began to complain of headache, which soon became persistent and gradually increased in severity, with some remissions and exacerbations. The temperature range was generally low, frequently 97°-98°, occasionally taking a sharp rise to 100°, 101°, or over, for a short time. The pulse was erratic, varying from 70 to 150. Is reported to have had some rigidity of muscles of neck for short intervals early in August. On August 12, had severe opisthotonos, convulsive seizures, loss of consciousness and retention of urine. Pulse ran to 150, temperature 99°. Noguchi test for butyric acid in spinal fluid positive. Pulse dropped to 100 and temperature to 98° following withdrawal of fluid. About ten days later symptoms again became active. Removal of fluid failed to give relief. Succinamide of mercury, gr. 1, given August 28. Apparently slight relief from symptoms. Repeated with 1.2 grains August 31. This was followed by marked relief of symptoms. With slight show of return of symptoms this was repeated Sept. 7, gr. 1, and 16, gr. 8. Patient left hospital Sept. 17, 1912. At last report was without marked return of symptoms.

This was apparently a case which was subacute from the beginning, the first symptoms having become manifest about six weeks following operation on tuberculous organs.

CASE III.—E. M. W. Referred from the office of Dr. H. G. Brainerd by Dr. Stephen Smith. The following is abstract of history from Dr. Brainerd's office: Dec. 30, 1910. E. M. W. Female. Single. Age 32. Bookkeeper. Normal weight 140 pounds. Has lost weight rapidly of late, most during the past three weeks.

Complains of weakness, numbness of left hand, and "nervousness."

History.—Always delicate. Severe malaria in childhood. Suffered severely with facial neuralgia for several years. Lupus of face for 12 years—three foci. Treated with *x*-ray and Finsen Light. Remains well after 9 years. Typhoid fever, 1908. Pulmonary hemorrhage, 1909, one year ago. Weight reduced to 122 pounds. Improved, some gain in weight, slight cough, no fever until about 3 weeks ago, when began to lose weight rapidly.

About three weeks ago, Dec. 10, stooped over, and was unable to arise without help. Soon felt better. Next morning sister (who is nurse) found her lying with arms extended and rigid, fingers clenched around thumbs, was very restless and nervous. Four days later loss of consciousness accompanied by mumbling and heavy breathing, no twitching. After two weeks right arm relaxed, but the hand is numb and weak with some pain along back of hand. Left arm less improved, much tenderness inner side of left arm; numbness and weakness much more pronounced in left hand than right.

Mental condition impaired since present exacerbation began three weeks ago. During this time has had chills at irregular intervals and fever reaching as high as 101 degrees. Appetite abnormally great, bowels regular, sleeps poorly.

Present Condition.—Dec. 30, 1910. Much demented. Tests of sensation not wholly reliable on account of mental confusion, but all seem to be more blunted in left arm and hand than right, station fair, co-ordination very poor. Same is true in less degree of left leg and foot. Wrist and elbow jerk greater on left side than right, also knee and ankle jerk greater on left side, but less than in upper limb.

FIG. 8—L. W., photograph taken May, 1910, five months after recovery from the active symptoms of measles; eight months after beginning treatment. Note slight strabismus and ptosis of left eye.

According to notes, the above conditions appeared to

increase slightly with remissions and exacerbations until Jan. 15, 1911, when patient was taken with hiccough. Right eyelid dropped. Left eye turned in. Conscious. Muttering speech. About fifteen minutes following onset of these symptoms patient fell asleep for a time followed by increased mental dullness, with increased impairment of left hand, arm, and lower limb—intensity being in the order named. Slight amelioration of symptoms after twenty-four hours.

Similar attacks occurred on the 19th and 31st inst., the last one being preceded by metallic taste in mouth.

Jan. 25. Wassermann test by Dr. Warden reported negative. Feb. 13. Paresthesia around mouth, talks with difficulty, tongue thick. Drinks with difficulty. Feb. 20. Very restless, distressed, and depressed. Growing weaker. Weakness more pronounced on left side, most left hand. Paresthesia around mouth more troublesome. Talks thickly. Sleeps with mouth open. Temperature variable, but subnormal most of the time, 97°-98°. Pulse 90-100. Believed to be tuberculous.

Nov. 11, 1911. About three months after beginning of symptoms of present attack, she presented herself at my office, accompanied by sister. She was much depressed mentally; would sob and tears start when I attempted to obtain history from her, and appeared to be incapable of answering questions intelligently. Complained of numbness in hands, arms, and lower limbs, most pronounced on left side—would rub left hand and say "It has gone away." There was some ptosis. Her facial expression was blank and stupid; would wander away if not watched. Muscle power was much reduced in both hands, almost absent in left; gait unsteady, imperfect use of both lower limbs, the use of left limb being much more impaired than right. Would fall easily, if not assisted while walking. Reflexes as given above. Weight 137 pounds; loss of 16 pounds during three months. Temperature range, oral, 97°-98°. Pulse 80-90. Physical examination of chest showed evidence of fibrosis in the upper lobes of both lungs, most extensive in right where cavity signs were apparent about second and third ribs. Cutaneous tests promptly positive, lumbar puncture not made.

FIG. 9.—L. W., in good health after 4½ years. Slight external strabismus still exists, the only remaining manifestation of the disease.

Watery extract of tubercle bacilli was used, beginning March 6, with .001 mg. doses, which were gradually increased to .01 mg. in about two months. Focal reactions were easily excited, as evidenced by temporary exacerbations of symptoms and signs of increased degree of paralysis. The symptoms and signs began to improve and continued uninterruptedly until at the end of two months her muscular impairment of function and mental condition were greatly improved, and she had gained about 10 pounds in weight.

May 4, referred to Dr. Brainerd for examination. The following is from his record: "May 4, 1911. Patient has been taking tuberculin treatment under Dr. Browning. Weight has gone up to 145 pounds. Mentality and spirits greatly improved, pain in arm better. Condition and use of arm better. Sleeps well. Some recurrence of symptoms after several of the injections of tuberculin. Patient looks cheerful and bright, talks well. Very little difference in reflexes on the two sides."

She continued under treatment for a year, with steady improvement, until by the end of six months she could come to my office alone. Her muscular system never entirely regained its former condition, but she walks well enough to get around without danger or attracting marked attention. Temperature gradually approached normal—97.6°-98.4°, and her weight increased to 157—gain of 20 pounds. No forced feeding. She gradually lost her sensitiveness to tuberculin and felt much better for about five days following a dose, which was 10 mgs. of watery extract. The interval between doses was gradually increased, she being instructed to return whenever she felt toxic. This she did, returning at intervals of from one week to three weeks for another year, until treatment ceased, she having nearly regained her normal condition, and so continues to the present time, about 3 years later.

This case apparently was a moderately acute meningitis terminating in a chronic form, followed by an arrestment.

CASE IV.—Sept. 22, 1909. L. W. Female. Age 2 years 9 months. *Family History.*—Youngest of family of three children. Maternal grandmother died as result of accident, other three grandparents living and well—ages 61, 63, 67. Father and mother aged 39 and 37 respectively, two brothers 4 and 7 years. Patient well until "severe cold on lungs," Jan. 18, 1909—two years of age. Coughed very hard, recovery incomplete. July 7, 1909, went on picnic, became exhausted, and grew progressively weaker, appetite poor, cough aggravated, had fever and night sweats.

Aug. 9. Mother states left eye disappeared, "went up and out." Consulted oculist. Systemic symptoms grew progressively worse, but eye made some improvement; external strabismus continued. Aug. 13. Mother noticed she was losing use of right hand, and that she fell frequently when attempting to walk; soon noticed dragging of left foot, followed by abandoning all efforts to walk. Used electricity for a few days, when noticed "both eyes began to close." Aug. 20. Taken to clinic, seen by Drs. Dudley (oculist), Chas. Lewis Allen and Ross Moore (neurologists). Ptosis both eyes, more pronounced in left, with marked degree of paralysis in right arm and hand, slight in left hand, with marked paralysis in lower limbs, was observed. There was evidence of lesion in apices of both lungs, and continuation of symptoms noted above. Syphilis was believed to have been eliminated, and after careful observation of symptoms and signs until Sept. 22, the case was referred to me as probably tubercular meningitis.

Examination showed enlargement of cervical glands, evidence of tubercular involvement of both apices, more marked in right. Moro and von Pirquet tests promptly and very actively positive. Began the use of watery extract of tubercle bacilli in doses of .000,001 milligram, which was cautiously increased. Several times evidence of focal reaction was observed as noted by temporary exacerbation of physical signs during course of treatment. Marked improvement was manifest at once, as shown by amelioration of symptoms and rapid improvement of signs.

Dec. 19, 1909. The child had an attack of measles, and soon the former signs began to manifest themselves.

The signs gradually disappeared however. Maximum dose of watery extract given was 2 mgs.

May 5, 1911. Continued good health after two years.

The temperature in this case was taken per rectum, and was somewhat erratic. At times it would reach 102°, but more frequently was subnormal. The daily range generally did not exceed one and a half degrees.

1004 STORY BUILDING.

SYPHILIS OF THE LUNGS SIMULATING PULMONARY TUBERCULOSIS.

By JOSEPH BLINDER, M.D.,

MONTEFIORE HOME AND HOSPITAL,

NEW YORK.

SYPHILIS of the lungs occurs more frequently than generally appreciated. It is quite often treated as phthisis and its frequent association with pulmonary tuberculosis renders its diagnosis more difficult.

According to J. K. Fowler the following four conditions are necessary for a sure diagnosis of the syphilitic nature of a lung lesion: (1) The case must be complete, that is, the symptoms observed during life must be considered in connection with the lesions described in postmortem findings, when such are available; (2) evidence of syphilitic infection must be undoubted; (3) repeated examination of sputum invariably negative for tubercle bacilli and absence of tubercle from the lungs must be proved by postmortem examinations; (4) syphilitic lesions, about the nature of which there can be no doubt, must be found in other organs.

With the exception of the postmortem findings, as our patient was fortunately cured with antisyphilitic treatment, all these conditions were met in the following case. The fact that the patient was diagnosed as pulmonary tuberculosis by competent clinicians before admission to the Montefiore Home Hospital, and was considered for a time as such in this institution, makes it worth while, I believe, to report the case.

Mr. G. J. H.—Born in United States, a traveling salesman by occupation. His father died of apoplexy at 62, and mother of carcinoma of the breast at 58; does not remember any diseases of childhood; has used alcohol in moderation and tobacco to excess (about fifteen cigars daily); has led more or less of an irregular life because of the requirements of his occupation. His appetite has always been good, bowels regular, and urination normal; had influenza two years ago; fistula in ano two years ago; gonorrhea at sixteen, complicated by a stricture, which was treated with bougies; syphilis denied. He married four and a half years ago a healthy girl of twenty. His wife and one child, four years old, are alive and well. No history of abortions or miscarriages.

Present Illness.—The onset was rather sudden, it dating back to about one year before admission when

FIG. 1.—Showing dense hilus infiltrations.

patient began to complain of cough, shortness of breath (especially on exertion), afternoon fever, night-sweats, and general weakness. He was losing weight in spite of remaining in bed on advice of his physician. During the following year the symptoms were gradually aggravated, and he lost altogether twenty pounds in weight. He then applied to this institution and was admitted on February 6, 1914, with the following chief complaints: Chills and fever, cough, night-sweats, general weakness, loss of weight (twenty pounds in one

FIG. 2.—Showing improvement following specific treatment.

year), pain in the back, in the calves of both legs, and in the lower part of the chest anteriorly.

Physical examination on admission showed a fairly well nourished and developed man; 145½ pounds weight. Height 5 feet and 7 inches. His best weight, one year ago, was 165 pounds; no edema, slight dyspnea, and cyanosis of both hands and feet; no gross anatomical deformities. Both pupils are regular and reacting to light and in accommodation; the left pupil is somewhat larger than the right; scar of a healed fistula in ano. His chest is barrel shaped, fairly symmetrical. Both infraclavicular fossæ are retracted, more marked on the right side; expansions equal on both sides. On percussion dullness was elicited over right apex anteriorly. Over both bases for three interspaces the resonance was defective, breath sounds diminished, and crepitant râles were heard on the right side posteriorly; percussion and auscultation of the heart negative, except for an accentuation of the second aortic sound. The maximum systolic pressure was 130. Physical examination of the abdomen showed an enlarged liver four fingers' breadth below the free costal margin; spleen and kidneys negative. The cervical and inguinal glands were palpable; the epitrochlear and others could not be felt. Two small round scars were present on the anterior surface of the left leg. His knee-jerks were exaggerated, but none of the abnormal reflexes was elicited. The urine analysis showed no albumin, no sugar, no casts. Fourteen examinations of the sputum, including three with antiformin, failed to reveal the presence of tubercle bacilli. The blood examination showed the following: Hb, 80 per cent.; red blood cells, 4.8 millions; white blood cells, 13,500; neutrophiles, 68 per cent.; lymphocytes, small, 19 per cent.; lymphocytes, large, 12 per cent.; eosinopnites, 1 per cent. The temperature varied between 101.4° in the afternoons to 98° in the mornings. The pulse 110 to 80, and respirations 30 to 20 per minute.

Unfortunately no *x*-ray plate could be obtained on admission, the radiographic laboratory not being complete on account of the recent moving of this institution to its new quarters. Two *x*-ray plates were taken by Mr. Scholtz, one about two weeks after treatment and another just before the patient left. It will be observed on the first radiogram that both hilus regions show very dense infiltrations, especially at the right side. The infiltrations seem to extend downward toward the base. The diaphragm on the right side is about one-half interspace higher than it normally should be. It also shows a bulging of its middle third, pointing to a pathological condition (gumma?). A slight dilatation of the aorta is also seen. That the lesions cleared up as a result of antisyphilitic treatment will be seen from the second radiogram. Both lungs appear to be much clearer. The infiltrations about the hilus and bases are less marked.

The patient was kept in bed. The afternoon fever and all the other symptoms mentioned above persisted in spite of the usual treatment. On February 25, 1914, a Wassermann test was performed and was found to

be triple positive. The patient was then again questioned as to his venereal history, and he admitted that about seven years ago he had a small round sore on his lower lip, which was diagnosed at a hospital as a chancre. He received antisyphilitic treatment for only one week and gave it up on account of a bad stomatitis, and as no symptoms of secondary syphilis appeared he forgot all about it. Antisyphilitic treatment was now begun, consisting of one grain of mercury salicylate intramuscularly administered weekly and increasing doses of potassium iodide. It was found that he could not tolerate more than 20 grains a day of the latter. However, this treatment was immediately effective. The afternoon fever subsided, the night-sweats stopped, the cough and pains disappeared. Within two weeks the patient, completely afebrile, was permitted to leave his bed. His general condition improved and he gained 17½ pounds in the two weeks following.

On April 10, 1914, another Wassermann test was performed and again found to be positive. An intravenous injection of 0.6 gram of salvarsan was then given. A rise in temperature and general malaise were observed for two days, but he soon recuperated and gained two more pounds in weight in the subsequent week. On May 7, 1914, a physical examination of the lungs showed them to be absolutely negative, and the patient was discharged cured.

Diagnosis.—The history of a chancre; the positive Wassermann reaction; the failure to improve on ordinary dietetic and hygienic measures; the gumma of the liver (as shown by *x*-ray); the symptoms and the pulmonary signs; the failure to reveal the specific microorganism of pulmonary tuberculosis on repeated sputum examinations, and the quick response to antisyphilitic treatment led us to believe that the case was one of pulmonary syphilis. The pulmonary lesions in this case being rather diffuse and confined mostly to the bases and around the hilus show it to be syphilitic pulmonary fibrosis.

A résumé of our experience in this case shows that with the exception of hemoptysis all the cardinal symptoms of pulmonary tuberculosis were present, namely, chills and afternoon fever, night sweats, cough, chest pains, and loss of weight. The physical signs, too, showed the presence of a rather moderately advanced lesion of the lungs. It is no wonder, therefore that this patient was considered tuberculous for over a year, and because no antisyphilitic treatment was administered, he continued to lose ground under the ordinary hygienic and dietetic measures that were taken. What made us doubt tuberculosis in this patient was the fact that the sputum continued to be negative for tubercle bacilli on repeated antiformin examinations, although the symptoms and signs progressed. Furthermore the pulmonary lesions situated at the base made us still more suspicious. There is no doubt that many such cases are often overlooked. If every case with basal pulmonary lesions and negative sputum were carefully studied, we would probably find that syphilis of the lungs is not as rare as it is considered at the present time.

In conclusion I wish to express my sincere thanks to Dr. Siegfried Wachsmann, our medical director, and to Drs. Maurice Fishberg and Lee Kessel, attending physicians to the tuberculosis pavilion, for their valuable suggestions.

Bilateral Harelip and Congenital Bilateral Mucous Fistula in the Lower Lip.—A. H. Todd reports the case of a healthy male infant aged three months, whose upper lip showed a wide bilateral cleft, with marked projection of the premaxilla, but there was no cleft in the hard or soft palate. The lower lip showed two small depressions, symmetrically placed, at a distance of about ⅛ in. from the midline; they were just large enough to admit the point of a small probe, and occasionally a bead of gelatinous secretion could be squeezed out.—*Proceedings of the Royal Society of Medicine.*

PREVENTION OF SCHOOLROOM DISEASE AND DUST.

By C. WARD CRAMPTON, M.D.,

NEW YORK.

DIRECTOR OF PHYSICAL TRAINING N. Y. SCHOOLS

THE annual recurrence of measles, diphtheria, scarlet fever, common colds, influenza, and the like among school children, causes an annual loss of uncountable days of absence. The financial and educational losses can be only estimated. It probably exceeds the cost of over 40,000,000 school days per annum.

The method of prevention of these diseases has in the past mainly developed along the lines of exclusion of those suffering from contagious diseases, members of the family and suspects who have been brought into contact with sufferers. While this is partially effective and there have been developed excellent methods for the regulation of exclusion, the general problem will not be solved without reference to the two most important factors in the transmission of diseases, which are (1)

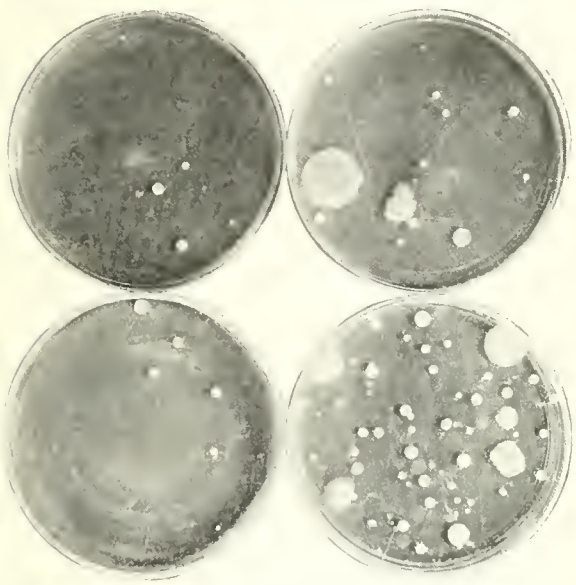

FIG. 1.—The two photographs on the left are from plates exposed in a room that has been treated with floor oil. The upper one before and the lower one after drills. The two on the right are from plates exposed in an untreated room, the upper one before and the lower one after drills.

an effort to prevent the dissemination of infectious material by coughing and sneezing; (2) the prevention of school dust.

Prevention of Coughing and Sneezing.—It is agreed that measles, diphtheria, scarlet fever, influenza and common colds are mainly transmitted by the expulsion of infectious material from the mouth and nose, in coughing, sneezing, and talking. At present, our school authorities have not arrived at the point of excluding every child from the classroom who had his first cough or sneeze, and it is at present doubtful if such a procedure would be warranted. The problem may be attacked very definitely by an effort on the part of the teacher to control coughing and sneezing in so far as it lies within her power.

A form circular was issued to the New York Public School Teachers, reading as follows:

"1. Scarlet fever, measles, diphtheria, influenza, and common colds are often spread by coughing and sneezing. This occurs frequently before the child appears to be ill.

"2. When a child coughs or sneezes he is apt to expel into the air visible droplets or an invisible spray containing bacteria and other germs which cause the diseases above mentioned.

"3. Children should be instructed as follows: (*a*) Each child should be urged to provide himself with a clean handkerchief. They should be carried conveniently so that they are available for immediate use. (*b*) Children should be instructed, when coughing or sneezing, to guard the mouth and nose with a handkerchief, so that none of the infectious material will be cast upon his associates or distributed throughout the room. The impulse to sneeze is often so sudden that this cannot be done. The child should, therefore, get into the habit, when he coughs or sneezes, of turning the head away from his neighbors and should guard the mouth and nose with the hand, but every effort should be made to make proper use of the handkerchief.

"The most recent medical investigations have demonstrated beyond doubt that the diseases mentioned above are transmitted by coughing and sneezing, and that these precautions against infection will do much to eliminate them."

It is impossible to tell exactly how much good this has done. Without implying a definite causal relation, it is interesting to note that the number of cases of scarlet fever reported from January 1 to June 14, 1913, is 2,724 less than the average of the preceding two years. The number of cases of measles for a similar period is less by 2,367.

Dust Prevention.—The definite causal relation of dust and disease has recently been disclosed in an endeavor to place before the medical and lay public the rôle of droplet infection.

The pendulum will not, however, swing too far in that direction in the minds of those who are familiar with the methods of classroom education. Most classrooms have wooden floors, which are (supposed to be) swept every day, and are scrubbed from two to ten times a year. The floor may be perfectly clean at the beginning of the school session and yet upon the entrance of the first pupil, it becomes dusty. Moreover, every movement of the child about the room during their physical training exercises and marching, causes the dust to rise in miniature geysers from the cracks which have not been reached by the broom of the janitor.

Immediately after the physical training exercises the air of the room is thoroughly saturated with dust which is breathed by the children and can be seen upon the handkerchiefs from blowing the nose shortly after the close of the exercise. Dirty dust is by no means a favorable lining for the nasopharynx, and none of the most enthusiastic of the adherents to the droplet infection theory (of which I am one) will claim that it is innocent.

It has been the good fortune of the writer to have been authorized to conduct a series of experiments of dust prevention in the New York public schools, for the purpose of ascertaining whether or not a sanitary oil floor dressing might be effective.

Five years ago the use of floor dressing was common. In many schools it has been discontinued because the careless use of large quantities, allowing a little oil to remain on the floor, dirtied the dresses of the teachers and made the floors slippery. In addition it was claimed that the oil-impregnated floors increased the fire hazard.

The opinion of the Bureau of Fire Prevention of the New York Fire Department is to the effect that any oil dressing may be used on the floors if the flash point is not more than 150° F. Accordingly this was taken into consideration and a dressing of a flash point of 300° was selected. In addition the experimenter used an applicator in the form of a small reservoir with a felt mop inserted at the bottom for the purpose of evenly distributing the material. The results in so far as teachers, janitors, and principals were concerned, were highly favorable. The results from the bacteriological standpoint are shown in the following bacteriological report from Wallace A. Manheimer.

(From the laboratory of the Department of Bacteriology, College of Physicians and Surgeons, Columbia University, New York.)

Tests were made:

1. Before and after conducting physical exercises, both in rooms that had, and in others that had not been treated with the oil.
2. Before and after these rooms had been swept.
3. On experimental boards (artificial floors) kept under controlled conditions in a large bell-jar.

Four rooms of like dimensions were selected for the tests. Two of these had been treated with the floor oil on November 28, 1913. The oil had been applied by means of a mop and added so that no excess of the oil remained on the surface of the floor after treatment. The other two rooms had not been treated, though they had been swept daily using sawdust soaked in the floor oil. The tests were conducted in Public School 42 on January 16, 1914, the oil having been in use since November 28, 1913, or 58 consecutive days without renewal.

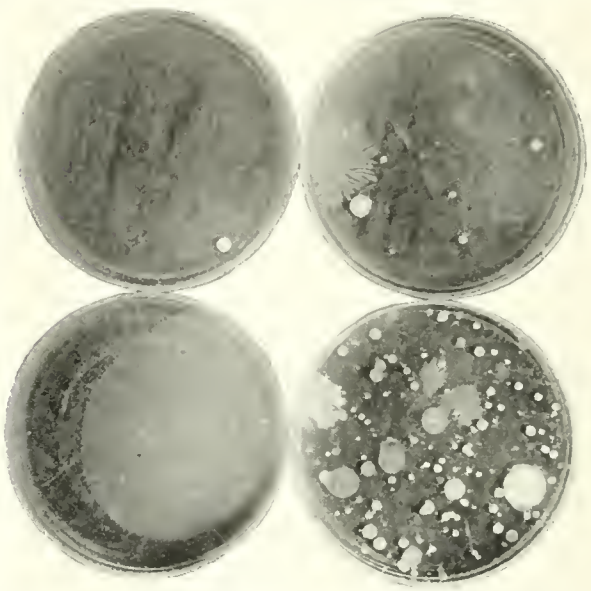

FIG. 2.—The two photographs on the left are from plates exposed in a room that had been treated with floor oil. The upper one before and the lower one after the room had been swept. The two on the right are from plates exposed in an untreated room, the upper one before and the lower one after the rooms had been swept.

Technique of Analysis.—Apparatus used. 1. Standard meat infusion agar petri dishes, sterilized in the autoclave for thirty minutes at 15 pounds pressure. 2. Quartz sand filters, sterilized in the hot-air oven at 160° C. for 1 hour. 3. Vacuum drum, the gave of which was calibrated. 5,625 c.c. of air were aspirated in all tests.

Plating and incubating. Exposure plates, and pour plates were incubated for five days at 20° C. Ten plates that had not been exposed were also placed under the same conditions. These plates were carried to the school, and from classroom to classroom, so that they would be actual controls. In these ten plates but one colony developed, so that the error in counting was 1/10 of a colony for each plate, a factor that is negligible.

The sand filters were emptied into 5 c.c. of sterile normal salt solution, rotated between the hands thirty times, and shaken with a rotary motion thirty times. One c.c. of this solution was then added by means of a delivery pipette to 9 c.c. of salt solution. The first tubes used contained in each c.c. one fifth of the number of bacteria that had been caught in the sand filters, while the second tubes contained one fiftieth of the number of bacteria. One c.c. amounts were then added to sterile petri dishes, and standard meat infusion agar poured over. Duplicate plates were made for both dilu-

tions. Three of the filters that had not been used were run through as controls. In no instance was there contamination, thus insuring the sterility of the filters, salt solution tubes, and culture media.

Tests: I. Before and After Drills.—A. Before drills. Students in the four classrooms (two treated with floor oil, and two untreated) were required to sit very still. Agar plates were exposed for five minutes in each room, and the dust contained in 5,625 c.c. of air caught in the sand filters. The sand filters and agar plates were held the same distance from the floor during all tests.

B. After drills. Identical tests as in A (above) were conducted after the floors were disturbed by physical exercises. In order to reduce the error introduced by drilling a large class of students, the following precautions were observed:

a. The same class of boys was used for drilling, both in rooms 204 (not treated with the oil) and 413 (treated with the oil), so that the results derived from these two rooms would be comparable. A different class of boys was used for both rooms 203 (untreated), and 414 (treated). Hence two sets of comparative data were collected.

b. Exercises that involved the feet only were conducted, *e. g.* springboard jumping, marching, etc., so that dust from the clothing of the students which otherwise would have risen into the air, was largely prevented from so doing.

c. The same drill was conducted in rooms 204 and 413, and a similar one in rooms 203 and 414. The same number of counts, same length of time, same exercises, etc., were used throughout. Hence the data of room 204 and that of 413 were comparable, as were those of 203 and 414.

TABLE NO I

Room No.	A. Before Drills			B. After Drills	
	Oil Used	Plate Exposure Count	Aspiration Count	Plate Exposure Counts	Aspiration Counts
204	No	3	5	74	90
413	Yes	2	10	18	14
203	No	8	25	108	105
414	Yes	6	12	17	20

(Note: By reading the table from left to right, the difference in air contamination before and after drills may be observed. By reading the table from above down, especially the second half, the efficiency of the floor oil may be readily observed as indicated by the difference between the counts when the oil was and when not used.)

By reference to the table (A section) it will be seen that the counts made from samples taken from the four rooms *before* the floor was disturbed by physical drills, were somewhat different. In the two rooms that had not been treated, the counts in the exposure plates were 3 and 8 respectively, and the counts on the pour plates, taken from samples collected from the same rooms, were 5 and 25 respectively. In the two rooms that had been treated the counts on the exposure plates were 2 and 6 respectively and on the pour plates 10 and 12 respectively. It will be seen that there was a little less dust in the rooms that had been treated than in the rooms that had not, even though the air had not been stirred.

By referring to the B section of the table and also to the accompanying photographs of the exposure plates, it will be seen that after drilling there was a marked difference in air contamination between rooms that had been, and those that had not been treated with floor oil. In the two rooms that had not been treated with the oil, the bacterial counts from plates exposed after drilling were 74 in room 294, and 108 in room 203, while in similar rooms that had been treated with the floor oil, using the same drills, etc., the counts were 18 and 17 respectively. It will be seen that under this rigid test 80 per cent. of the bacteria that would have arisen into the air were prevented from so doing by the floor oil. (Computation made as follows:

$108 - 17 = 91$, $\frac{91}{108} = 84$ per cent. and $74 - 18 = 56$, $\frac{56}{74} = 76$ per cent. $\frac{84 + 76}{2} = 80$ per cent.)

Moreover on the day the tests were made, the weather was quite damp, and therefore much moisture had been tracked in by the feet of the students. It is confidently felt that an even greater percentage of efficiency would have been obtained had the day been clear and dry. It must be borne in mind, also, that any dust from the clothing of students operated to increase the number of colonies on all plates alike. This introduces an error into the analysis which operates to increase the value of the denominator in the above fraction, thus lowering the value of the fraction as a whole. If a simple hypothetical case be selected this error can be made clear. Suppose the bacterial counts in the treated and untreated rooms were 30 and 100 respectively, exclusive of the bacteria that might have come from extraneous sources (*e. g.*, clothing of the students, etc.) over which the oil can have no control; and that furthermore the bacteria added to the plates from these extraneous sources amounted to 10 in both rooms. Computing the efficiency without adding this error factor, we have

$$100 - 30 = 70 \frac{70}{100} = 70 \text{ per cent.}$$

adding in the error factor, we have

$$110 - 40 = 70 \frac{70}{110} = 63 \text{ per cent.}$$

In other words, the error factor reduces the percentage of efficiency in this hypothetical case by 7. When dealing with small figures as in the above colony counts, this error must be large. Hence 80 per cent. is an underestimation of the efficiency of floor oil in preventing dust from rising from the floor.

In the tests made from the filters, where more accurate data were obtained, the efficiency computed as above was 82½ per cent. The same error factors enter here as in the above tests, hence the efficiency must be considerably greater.

II. Before and After Sweeping.—(Note. The tests made before sweeping were exactly the same as those before drilling, therefore they will not be repeated below.)

A. Before Sweeping	B. After Sweeping		
Omitted (See Table No. 1)	Room No.	Oil Used	Plate Exposure Count	Aspiration Count
	204	No	223	90
	413	Yes	23	15
	203	No	263	50
	414	Yes	33	5

Efficiency average on exposure plates 86⅓%
Efficiency average on aspiration plates ..... 84 %

The results here are particularly interesting, because less dust from extraneous sources, (*e.g.* the clothing of the children, etc.), was raised into the air. All the tests made were identical with those mentioned in the preceding section. The same sweepers were used in the four rooms and the time taken for sweeping was the same in each case. The untreated rooms were swept first, so that the amount of dust on the brooms and clothing of the workmen was less here than in the treated rooms. Thus the bacterial counts obtained were somewhat higher than they should have been. It is therefore evident that the percentage of efficiency as indicated in the above table and photographs, though high, is somewhat less than it should be.

In spite of these error factors, however, operating against the estimated efficiency of the floor oil, the tests here showed up favorably. From the accompanying photographs and the above table, it will be seen that the efficiency is high. In the untreated classrooms the counts were 223 and 263 respectively, while in the similar rooms that had been treated, the counts were 33 and 23 respectively. The computed averages in both sets of tests gave efficiency percentages of 84 and 82½. Hence the value of the floor oil is great, in protecting not only the health of pupils and teachers during the performance of the regular class work, but also that of the workmen employed in sweeping the floors after school hours.

III. Tests on Experimental Boards (Artificial floors). Two sterilized boards (8″ x 12″), one treated and the other not treated with the oil, were each painted with two cubic centimeters of an emulsion of *Bacillus prodigiosus*, and allowed to dry for seven days in wire baskets wrapped in paper. They were then

placed at different times in a large glass bell-jar and subjected for forty seconds to the draught of an electric fan. Plates were then exposed in the bell-jar, and aspiration counts made exactly as was done in the two tests above. After allowing the bacteria on the plates to grow for five days, the pigmented colonies were counted.

The results of this experiment are as follows:

	Exposure Count	Aspiration Count
Rooms not treated with floor oil	12	3
Rooms treated with floor oil	1	0

Hence it will be seen that the efficiency percentage varied from 91 per cent. to 100 per cent. when judged by tests made on experimental boards. Since the factors here were under control, and since no error factors entered, the results show the efficiency of the oil in preventing the raising of dust.

Summary.—No. 1. After the oil had been on the floor for 58 consecutive days without renewal, the following tests were made; these tests (made to determine the efficiency of floor oil in preventing the raising of dust before and after conducting physical drills, both in rooms that had been and in others that had not been treated with floor oil) showed:

(*a*) That there was less dust in the treated than in the untreated rooms even before the floors were disturbed, though the differences were not marked.

(*b*) That the oil was efficient in causing more than 80 per cent. of the dust to adhere to the surface of the floor disturbed by physical exercises.

2. Similar tests made before and after the rooms had been swept, indicated an efficiency of over 85 per cent. Thus the oil is valuable in protecting not only the health of teachers and students, but also that of workmen employed to clean the rooms.

3. Tests made on experimental boards (artificial floors) under controlled conditions, verified the above conclusions and indicated an even higher percentage of efficiency (91 per cent to 100 per cent.)

157 East Sixty-seventh Street.

OBSERVATION ON MALARIAL FEVER*

By L. SEXTON, B.S., M.D.,

NEW ORLEANS, LA.

THE rational treatment of malaria of the tertian type resolves itself into ridding the red blood cells of the asexual *Plasmodium malariæ* injected into the blood stream by an infected anopheles mosquito.

No treatment of malaria is worth while that does not take into consideration the eradication of plasmodium in the blood, or protection of the patient against the anopheles mosquito.

Whenever a fever case is visited in a malarial section several blood smears should be taken during the first visit before the administration of quinine, so that with the clinical symptoms a positive diagnosis may be made at once. This is particularly true during times of typhoid and suspected yellow fever, as there is no differential diagnosis harder to make without the microscope than between the malignant forms of malarial, yellow, and typhoid fever. Many practitioners in the South very properly carry their microscopes along to the bedside to examine such blood before any treatment is begun.

In tropical countries an examination of the blood for malarial parasites should be made of all subjects suffering from coma, uremia, and dysentery, as the cause of the trouble found early, if malarial, may be the means of saving a life by prompt treatment at the proper time.

The crescent parasites of the pernicious form of malaria are hardly recognizable except by an expert microscopist, after staining, as the evidence is often only small specks of protoplasm with little or no pigment. When these sporulating plasmodia segment liberate a toxin which is the cause of the nervous explosion or chill, the severity of which depends upon the amount of toxin set free in the blood at the time of sporulation.

The remittent type of malaria is due to the estivo-autumnal form of parasite. The paroxysms are much longer in duration, running into each other so there is no cessation from fever. Such types may be mistaken for typhoid or yellow fever unless the discovery of the plasmodium in the blood or Widal should clear up the diagnosis.

Prevention.—Not within our generation need we expect the eradication of malaria, and this on account of the lack of education and the carelessness of the average physician and parasite carrier. It can be, and has been modified in many communities by the building of residences on the highest part of the farm or town and screening them. Residences should be removed from nearby pools of water and swamps; then by draining and oiling of ponds, or stocking the ponds with numerous fish; by using the essential oils and mosquito lotion on all exposed portions of the body, particularly after night, when the anopheles are most active, many outbreaks of malaria might be prevented. Exposure at night should be avoided, sleeping under a close mesh bar, taking three to five grains of quinine three times a day on alternate days, during the summer and fall months in malarial sections will reduce the infection to one-half or less of the present prevalence.

The night moving picture shows, the night court session, or any gatherings of rural people from malarial sections are among the most common sources of malarial infections.

Mosquitos prefer as a breeding place the small stagnant pool, tin cup filled with water, or borders of the river or lake fringed with weeds and grass to protect them. All these sources of breeding should be oiled in addition to screening and fumigating the infected house and screening the patient.

Drainage and sewerage lowering the water level, the abolition of cisterns in New Orleans has reduced the malaria in this city, until years may pass a busy doctor without having a case unless it is brought into the city or hospitals from the surrounding country.

Immunity to malaria seems to exist among natives and some of the children of the dark races who have been raised in malarial districts; many of these persons carry parasites in their blood, without having chills. Their immunity acquired or inherited exists against the toxins alone, not against the parasite. A probable explanation of this immunity is that on account of the peculiar odor of many of the black races mosquitos will not molest them. It is a known fact that the same odor will cause wasps to leave, and permit their nests to be robbed, as is a common practice among some of the dark races in the tropics where the young wasps are used for fish bait.

As said before, three to five grains of quinine on alternate days with meals, during the summer and fall months, is usually sufficient to prevent malaria, and in such small doses can hardly do any harm to those even with an aversion to the drug.

Quinine is germicidal to protozoa by first stimulating and then paralyzing them; from five to fif-

*Read before the Tangipahoa Medical Society of Louisiana.

teen grains daily according to the severity of the case is quite sufficient. Ten grains night and morning on the seventh, fourteenth and twenty-first days succeeding the last chill prevents relapses. One grain daily for each year of the child's age is a very proper dosage for children.

Quinine muriate is quickly absorbed, appears in the urine within fifteen minutes after it is taken into an acid stomach. Its greatest concentration in the blood is within three hours after its administration, hence, ten grains should be given from three to four hours before the expected chill in the adult so as to meet and destroy the young parasites when they are least resistent to its action.

Euquinine is the tasteless carbonized acid of quinine and may be given to children in chocolate, sugar, or milk, and is so insoluble in the mouth that it is almost tasteless in the above mixtures. Its action and the doses are the same as those of sulphate and muriate, only more time is required for its action on account of its insolubility. Warburg's tincture is a compound of quinine, rhubarb, aloes, gentian, camphor, and essential oils, but its chief ingredient is quinine, and its better effect is due (to the stomach that can retain it) to the quinine being in solution and perhaps more readily taken into the circulation on account of the volatile oils stimulating its absorption. Half-ounce doses repeated in three hours usually produce profuse perspiration. It is more applicable to the remittent than to the tertian forms. It can be retained only by the strongest stomachs aided by giving crushed ice and applying ice to throat and mustard to the stomach.

When in children, or because of gastric irritation in grow-ups, quinine cannot be retained by mouth, a cleansing enema is given, followed by double the mouth dose of quinine in warm solution held in the rectum by compressing the anus for an hour, or until absorption has taken place. Suppositories of quinine made with cocoa butter are also recommended when it is impossible to retain the drug by the stomach. A preliminary cathartic of some agreeable form should always precede the giving of quinine in malarial cases. The reason many cases hang on for a season, become chronic, and cause doctors to proclaim that quinine is not a specific, is the constant reinfection of these patients by working in the same swamps, environments, and fields infested by these infected mosquitos. The proof of this assertion is the fact that members of the family similarly affected who go away to the mountains, or out of the infected territory remain well after taking quinine on the seventh, fourteenth and twenty-first day after the last chill; while those who remain in the infected territory become reinfected unless kept screened and under the influence of quinine all the time.

In quinine we have a specific drug to destroy these plasmodia. In red blood cells fairly filled with these plasmodia we find the plasmodia destroyed or absent, with clinical symptoms gone after three days' administration of twenty to thirty grains of sulphate of quinine, provided the drug has been absorbed and given at the proper time. These are facts known and demonstrated wherever malaria is known to exist. There are several theories as to how the quinine accomplishes this result, viz.: (1) that it produces an edema of the sick red cells, destroying the plasmodium in situ, or (2) increases phagocytosis, raising the opsonic index, or (3) sterilizes the blood so that plasmodia cannot multiply, or (4) directly paralyzing the organism in the blood. We are not particularly concerned as to which of these theories is correct; the main point with us is to know just how to cinchonize the patient the quickest way, thereby eradicating these poisonous germs from the blood of the patient entrusted to our care.

Anemia of malarial and tropical countries is almost universal. Pale people is the rule and not the exception; chronic diseases, hookworm, climate, and food play their part, but the destruction of the red cell by the malarial plasmodium is the principal cause of so much anemia in our Southern country. The cells may run down to two million per c.c., leaving the patient weak and dyspeptic and with all the symptoms attendant upon impoverished blood. Such patient should be kept in bed so long as fever continues and cinchonization should be accomplished as soon as possible to destroy the ameboid parasites. Iron and arsenic, bitter tonics with the most nourishing and digestible diet, bathing, elimination by kidney, bowels, and skin are essential. The patient should be kept in bed, fed on the most digestible food and removed from malarial climate as soon as possible. The ability of arsenic (iron, red bone marrow, and other tonics) to help build up these red cells destroyed by the plasmodium, has caused arsenic to be ranked next to quinine in its curative properties for malaria; but it is the tonic and not the antimalarial property of the arsenic that accomplishes the good result. Any treatment that would build up red cells as promptly would answer just as well. Fowler's solution pushed to its physiological tolerance, arsenous acid 1 60 grain doses, cacodylate of sodium, two to three grain doses; even salvarsan introduced into the blood stream does not destroy the plasmodium, but they do help materially in blood reconstruction.

It is related of the workers in a mine in Mexico, where the laborers come from the malarial coast country, that though they suffer from arsenical poisoning after working in the mine for some time, they continue to have the chills and arsenical poisoning at the same time, unless quinine is given the chills continue. So in the treatment of acute malaria no time should be wasted giving arsenic when cinchonization is what is imperatively needed. As a matter of course, arsenic has its place in the after-treatment as a nerve and blood tonic to follow up the eradication of the plasmodia by quinine.

When quinine capsules are given by the mouth they should first be punctured with a needle and followed by some acid drink to insure immediate absorption. Hard compressed pills and tablets may pass through the stomach without absorption and thus cause a failure of cure to be credited to quinine.

There is no occasion in any case to give 100 grains of quinine daily, as it is neither absorbed nor required, and may be toxic in over thirty grain doses during twenty-four hours. Fifteen grains of quinine makes a 1 5000 solution in the blood of the average patient. Twice this amount is quite sufficient to destroy all the plasmodia (not crescents) if given three days in succession. The quinine acts better when given in two or three, seven to ten grain doses, preceding the expected chill time by three or four hours, so as to have the maximum saturation of the blood to meet the newly-developed plasmodia as they occur in the blood at their most susceptible age to the action of the quinine.

Contraindications to Quinine.—Persons with defective hearing, middle-ear disease, and those who are very susceptible and nervous should be given the

smallest amount of quinine capable of destroying the germ. Many people have an aversion to quinine and its effect, in others it produces urticaria or disagreeable tinnitus aurium, while others seem much depressed by its use. Such patients should take the quinine in smaller doses or in combination with bromide of sodium or phenacetine, or some other control; but of the evils, quinine effects or malaria, the latter is much more potent for evil to any patient suffering with the disease.

No one should be graduated or licensed to practise who is not thoroughly familiar with the means of cure and eradication of malaria. Boards of health not working on the malarial problem should be superseded by men who know and will combat our greatest enemy. State and National legislatures should be importuned to support liberally all means for the eradication and cure of malaria. Where hookworm or yellow fever has infected one, malaria has infected its thousand.

Our philanthropists can do no better than to help in the eradication of the anopheles mosquito and the drainage and redemption of the lowlands that harbor this parasite. Every drainage canal and reclamation conference is a tack in the coffin of the great malarial scourge of many portions of the United States, for it must be remembered that nearly all inhabitants of our country are liable to the infection of the anopheles mosquito. So it is not local but national in its sphere, and is an important enough subject to command the attention of our greatest national leaders in every State of the Union.

From an economical standpoint, the eradication and control of malaria is the most important subject that physicians, boards of health, and drainage engineers have to deal with, for no malarial country can be considered healthy.

STATE-PREVENTION AND PULMONARY CONSUMPTION.

By THOMAS J. MAYS, M.D.,

PHILADELPHIA, PENNA.

Disease-prevention is the science which deals with those forces of nature that make for the enhancement of health. If one were inclined to be seriously impressed with a great deal of the sanitary preachments of the day the conviction might easily be formed that most if not all the advancement in health matters was accomplished by legislative enactments, and that all the future protection against disease will have to come through the same channel. With all due regard for these sentiments it must not be forgotten, however, that in spite of all the benefits which have been bestowed on the human race by health-laws and health-boards, there is and has been a more powerful force at work in the conservation of human life and health than all the health commissions in the world, from those of the Hebrews, Hindoos, Egyptians, Greeks, Romans, and of our own times combined. This is the force of adaptation, or the power that adjusts the body to the unfriendly and destructive forces residing in its environment—a struggle that is coeval with life itself.

This is the force that shortens the stem of a tree in an exposed position and lengthens the same when it grows in the forest; that enlarges the muscles, blood-vessels, and nerves of the blacksmith's arm, and of the dancer's legs; that amplifies the heart muscle under excessive physical strain; that assigns white flesh to the wings of the domestic fowl, and dark flesh to the same organs of its wild congener; and that bestows a dark skin on the dwellers of the tropics, and a light skin on the inhabitants of the high mountains.

In addition to the modifications which natural influences impose on man, he turns around and modifies his environment and this in turn reacts and changes him.

Man's natural love of comfort and well-being, coupled with a knowledge that it is safer to be healthy and wise than to be sick and ignorant, are powerful incentives to good and healthful conduct. He begins to protect himself from the raw elements of nature by providing proper shelter, clothing, and food. His primitive lodgings are transformed into well-ordered dwellings, built in salubrious locations, provided with comfortable furniture, and supplied with baths, drainage, sewerage, and other sanitary essentials. These developmental changes in his domestic and social conditions are brought about by a course of self-education in the first place and in the next place the practical results of these changes soon demonstrate to him that civilized influences not only provoke greater happiness, but prolong life.

These phenomena constitute the so-called transitional reactions which with their stimuli act and react on each other in the early social economy of the human race. And while these changes long antedate the existence of organized health regulations, it is very obvious that after the application of such laws sanitation becomes greatly enriched by reason of their assistance.

Now, in the application of these principles of prevention to pulmonary consumption it must not be overlooked that health enactments are but artificial means to further this process, the function of which is to stimulate and enhance the natural principles of sanitation, which long precede them. This is their normal province and it is only when the former venture to go beyond this line that they become dangerous and injurious.

In view of these considerations it is of interest to trace the effects of each method in operating against this disease. In doing this it must be remembered that no organized or official prevention efforts had ever been launched against this disease, in this country, until up to about the late nineties, yet from statistical proof gathered from the cities of Philadelphia, New York, and Boston, for a period of one hundred years, from 1812 to 1911 (Hoffman), it is made clear that from the beginning to the end of this period the death rate of this disease had been gradually declining, unaided by any direct measures, except during the last ten or twelve years—barring the period immediately preceding, after, and during the civil war, when it increased, or only showed a slight reduction.

Moreover, this collection shows that its decrease was 1 per cent. greater from 1832-1851 (12 per cent.) than from 1892-1911 (11 per cent.)—the latter period marking the time when the restriction-movement held full sway. But the most unfavorable showing of these figures for the prevention crusade is the disparity in the decrease between 1882 and 1901 and 1911. During the former interval, when nothing special was done in a preventive way, the death rate decreased 26 per cent. over the previous equally long interval, while during the latter, when the preventive movement was in its

greatest activity, there was only a decrease of 11 per cent., or less by 15 per cent., than during the former interval.

Furthermore, it is a cause for encouragement to know that Dr. Karl Pearson, Galton Professor of Eugenics in the University of London, an unrivalled biometrician, in his volume on "The Fight Against Tuberculosis and the Death Rate from Phthisis," fully corroborates the observation that pulmonary consumption has been on a gradual decline in England and Wales, until within recent years. He analyzed the death rate of general diseases and phthisis in those countries separately, from 1835 to 1910—a period of seventy-five years. He shows that so far as general diseases are concerned the death-rate falls very slowly during the first-third of the whole period, during the second-third of the period the fall is more pronounced, and this is continued during the last-third of the period. On the other hand, the fall in the death rate of phthisis is quite pronounced during the first-third of the whole period, more so during the second-third, and during the last third there is a pronounced check in its decline. In other words, the death rate of general diseases continues to decline at the same pace as it did during the preceding third, while the death rate from phthisis increased in the last-third instead of decreasing as it did during the preceding two-thirds.

From the above it is quite apparent that a reduction in the death rate of consumption has probably been going on in most of the civilized world independently of any special legislative regulation; and that since the introduction of official legislation on health matters, the death rate of this disease has actually increased. This is hardly credible in view of the tremendous efforts which have been put forth and the millions which have been spent in its behalf during the last ten or twelve years, yet facts clearly sustain this statement.

Still greater surprise may be expressed at the failure of this movement when it is stated that a recent example demonstrated very emphatically the possibility of making a marked reduction in the mortality of this disease in the course of very few years. Thus, in the American occupation of Santiago de Cuba in 1898 active efforts were made by the United States Government to get rid of yellow fever in that city, which was said to have been the filthiest city in the world. The foci of fever were cleaned and disinfected, cesspools, latrines, manholes, and wells were cleaned; cellars, floors, ceilings, and walls of houses were drenched and scrubbed, and all nuisances were strictly prohibited. In three years the deaths from yellow fever sank to zero, the general death rate sank from 133.71 to 6.00 per thousand, and consumption was reduced 67.00 per cent. There was no special care of consumptives, nor any disinfection of their sputum, neither was segregation of consumptives practised.

The real reason, therefore, for the disastrous failure of the present legislative crusade to crush out consumption lies in the fact that instead of investigating the probable influences which reduced the mortality of this disease very markedly in the past, or of studying the particular methods which so successfully prevented the disease in Santiago de Cuba, it was thought wise to institute a legal prevention measure which had been employed in Italy about a century and a half ago, and which after being thoroughly tested in that country for more than fifty years, was discarded not only as being absolutely worthless for preventive purposes, but because it inflicted indescribable injury and suffering.

After all is said and done the stubborn fact remains that if well-proven measures had been employed for the purpose of preventing consumption in place of importing the plagiarized, valueless Italian method, no one would have to perform the duty of pointing out the melancholy fact that for the first time in a hundred years this country was compelled to apply a procedure which was not only powerless to hold the mortality of this disease to the point to which it had been reduced by the preceding ordinary measures, but failed to prevent a decided rise in the same.

THE NECESSITY FOR PARENTAL COOPERATION IN THE EXAMINATION OF MENTAL DEFECTIVES.

By J. T. KRAUSE, M.D.,

Brooklyn, New York.

Examiner of Mentally Defective Children, Board of Education, New York City.

THERE has always been a certain percentage of the pupils in our public schools who have, for various causes, been unable to make normal progress in school. These pupils were, to a great extent, allowed to shift for themeslves. Nearly everyone of us can recall how the dunce of the class was made the target for the ridicule of the others. It is only of recent years that our public school system has seriously concerned itself in the various etiological factors which are directly responsible for the retardation of normal development. As a direct result of this new activity, an important innovation was made, namely, the formation of ungraded classes for mental defectives in various schools throughout the city.

Before a child is placed in an ungraded class several important steps are taken. Whenever the teacher has reason to believe that impairment of normal school progress may be due to some physical or mental defect, such cases are referred to the principal who in turn reports it to the city superintendent. All such cases come under the supervision of the inspector of ungraded classes who assigns a physician to examine and determine the mental status of the child reported. The physician's examination consists of a complete family and personal history, school record, physical and mental examination. It is not the intention of the writer to dwell upon the physical or mental examinations (which are described in detail in our latest medical works) but to show the important relationship between a complete family and personal history, and a correct diagnosis of the case.

In order to have a thorough understanding of the case, not only the child, but its antecedents must be studied. Who but the parents can supply such information? Other reasons why parents should be present at the examination will be described later. The family history is very important as it frequently shows a direct transmission to the child of some hereditary taint. The history of the grandparents must be looked into. Were they normal individuals? Did they reach a ripe old age? Is there any trace of insanity, tuberculosis or alcoholism among the brothers and sisters of either parents? Is there any trace of insanity, tuberculosis, syphilis or alcoholism in either parent? Has there been any consanguinity in marriages? The

value of such information is obvious. Much tact must be used in framing the questions so as to adroitly draw out this information without causing embarrassment. Having obtained a fair conception of the remote family history, the immediate family history is then in order; the number of births in the family, the number that have died, the cause of the death in each case, the educational attainment of each child. Such information will give the examiner an idea as to whether there are any inherent defects in the family.

The personal or developmental history is of utmost importance in studying the child. The mother usually can give valuable information, not only from the date of birth, but during the prenatal period. Frequently a mother will volunteer the information that at a certain period during pregnancy she was subjected to a fright or fall. Prenatal influences play an important rôle in studying the development of the child. The history of the child during labor should be ascertained. Was labor normal or was the delivery instrumental? If the latter, what damage, if any, was done to the child? If labor was protracted how did it affect the child? Was it necessary to resort to artificial respiration? It is important to ascertain the physical condition of the child at the end of the first year. Did the mother notice any peculiarity at that period? Did the child differ from other children at that age? Did the child begin to cut teeth, walk, and talk at the usual periods? One can readily appreciate the importance of such information obtained from the mother who has watched the child day by day. The diet during the first year is very important. Was the child nursed or bottle-fed? If the former, was the mother in good health? If the latter, what were the ingredients? The general health of the child during infancy must be ascertained. Did the child have any of the infectious or contagious diseases? Were there any complications and if so how did these affect the child? We all know that environment has a molding effect upon developing brain. The examiner must make inquiries about the home conditions. What are the environments at home? Are the sanitary conditions favorable to the normal development of the child? Does the child receive the proper hygiene? Is the child receiving a nutritious diet? Does the diet include harmful stimulants? With whom does the child associate? How does the child behave at home? The mother usually can describe the idiosyncrasies, if such are present, and which go to complete the picture of the child's development.

Aside from the fact that the parent can give a history of the case, the presence of the parent at the examination gives the physician an opportunity to study his or her mental caliber. Frequently the neurotic tendencies in the child are displayed by the parent at the examination. In many instances the examination of the child reveals certain physical defects which need correction. Certain errors in diet or hygiene which need adjustment. It is a simple matter for the physician to make these findings known to the parent with a view to ultimate correction. In order to have the cooperation of the parents, it is not only necessary to say "Your child has enlarged tonsils and adenoids," but to explain how this obstruction mechanically may be responsible for the mental sluggishness of the child. Parents must be educated and it lies within the domain of the examining physician to enlighten them on matters which are of vital importance. The presence of the parent at the examination seems to put the child at ease and within a few minutes the apprehensive and evasive child recovers his equilibrium. This is particularly the case when the child is of the neurotic type and shows the characteristic lack of emotional control. To gain the confidence of the child is by no means an easy matter unless the parent is there with a cheering word.

From the foregoing it can readily be seen how important it is to obtain the cooperation of the parents. Are the parents willing to cooperate with the examining physician in the interests of their children? Unfortunately it has been my experience in examining the child in the public schools of Greater New York that quite a number of the parents are, for various reasons, indifferent to the school progress of their children. This is particularly true where great poverty exists and where both parents are the bread earners. In other cases I have learned that owing to the large number of children at home, the mother is unable to spare the time to accompany the child to the examination. In a very small percentage of the children examined in the public schools are the parents present whereas those children examined at the clinics held in the New York and Brooklyn offices generally are accompanied by their parents. This is simply due to the fact that notices are sent from the office of the Inspector of Ungraded Classes, urging the parents to be present at the examination. Were similar notices sent by the principals to the parents urging their presence, I feel certain that the results would be gratifying. Not only should written notices be sent out, but in smaller schools the teachers should be asked to make personal visits to the homes and explain the necessity for parental cooperation.

During the past year it has been my pleasure to have the assistance of the social workers connected with the Department of Ungraded Classes. In cases where poor home conditions prevented the mother from attending the examination, also where certain characteristics of various members of a family were to be studied, I have found the social worker's report invaluable. With such information at hand the examination of the child becomes comparatively simple and a correct diagnosis is easily obtained.

What steps, if any, can be taken to insure the cooperation of the parents with the school authorities? The importance of the parent's presence at the examination should be impressed upon the principals of the various schools. The era of indifference has gone by, and it is to them that we now look for assistance. It is through them that the teachers can be made to understand that a developmental history is far more important to the examiner than a school record. It is through them that the parents must be urged to cooperate. Social workers should be encouraged and their number increased. No child should be brought up for diagnosis unless a complete developmental history is available.

199 Hart Street.

Practising without a License—Separate Offenses.—Under the Texas statute, Pen. Code 1911, §756, providing that any person practising medicine in violation of law shall be punished, and that each day of such violation shall constitute a separate offense, a conviction of unlawfully practising medicine on a day in March is no bar to a prosecution for practising medicine upon another person on a day in May.—Byrd vs. State, Texas Criminal Appeals, 162 S. W., 363.

MEDICAL RECORD.

THE THERAPEUTIC USES OF SUGAR.

WITHIN recent years there has been a growing recognition not only of the dietetic but also of the medicinal value of sugar. As a quickly assimilable nutrient during the exhaustion following severe exertion and during fatigue, sugar constitutes an important article in the dietary of the artisan and of the soldier. Moreover, it has won a distinctive place in therapeutics, particularly in the treatment of shock, of postoperative acidosis, and of cardiac weakness; it has also been extolled as a local application in the treatment of ulcers.

Many observers have proven experimentally that the intravenous injection of a highly concentrated hypertonic solution of glucose causes an immediate and pronounced diuresis by virtue of the dehydration of the body cells, and that the injection of solutions containing from 25 to 33 1 3 per cent. of sugar in doses of 15 grams to every kilogram of the animal's weight is a safe procedure. E. Enriquez in the *Presse Médicale*, February 14, 1914, points out that this diuretic action is not the result of any special property of the sugar but is evoked similarly by all hypertonic solutions. Starling has shown that the injection of concentrated solutions of glucose is followed by an increase in the total volume of the blood, resulting from the attraction of water from the tissues, which increase is gauged by the diminution in the percentage of hemoglobin. There are likewise an increase in the arterial pressure and an increase in the volume of the kidney. These three phenomena are accompanied by an augmented urinary outflow.

Fleig first called attention to the feasibility of replacing the ordinary saline solutions by isotonic solutions of glucose, lactose, saccharose, or mannite. These solutions had a strength of about 5 per cent. Furthermore, he demonstrated clinically the diuretic power of hypertonic solutions containing 300 grams of sugar per kilogram. Enriquez essayed the use of intravenous injections of such solutions in fifty patients, in some of whom as many as thirty injections were given during the course of their disease. The solutions which were carefully sterilized were injected slowly into a vein at the bend of the elbow, one hour being taken for the injection of 250 to 300 cubic centimeters. There was no evidence of any intolerance on the part of the organism: there was, for example, no hemolysis as evidenced by the development of icterus. This benign effect is attributed to the slowness of the injection, and to the rapid transformation of the sugar into glycogen which is deposited in the liver, the muscles, and the myocardium. Under these conditions the proportion of sugar in the blood is kept within normal limits. Only very small quantities of the sugar, four or five grams at the most, pass into the urine, and that within the first two hours following the injection. It is suggested that *a priori* the injection of a large quantity of sugar into the blood of an individual suffering from a hepatic disorder would be followed by an immediate and a marked glycosuria. But actual experience proved otherwise: in two cases of alcoholic cirrhosis with ascites the introduction into the blood of 150 grams of sugar at one time caused no more pronounced or persistent glycosuria than that which followed in the average case. Besides, examination of the blood did not show any change in the red blood cells.

The value of intravenous injections of hypertonic solutions of glucose was demonstrated in a large number of cases of infectious diseases in which there was a partial suppression of urine. In these cases a pronounced diuresis was produced. A severe case of carbon-monoxide poisoning was apparently rescued by the use of this measure. Similarly in cases of inanition resulting from stenosis of the esophagus or pylorus, in cases following prolonged anesthesia, in cases of oliguria secondary to cardiac weakness, and in cases of chronic nephritis, the injections of glucose produce good results. The chief value of glucose lies in its tonic action on the heart muscle and in its diuretic power.

THE PULSATING PLEURISIES.

ALTHOUGH of rare occurrence the phenomenon presented by a pulsating pleural exudate is of sufficient interest to merit more than ordinary attention. Very brief mention is accorded to this condition in the various textbooks, and then only in connection with the differential diagnosis of thoracic aneurysm. A comprehensive discussion of the subject of pulsating pleurisies is contributed by M. Paillard and J. Quiquandon in the *Gazette des Hôpitaux*, June 13, 1914. It is pointed out that in most instances the pulsating exudate is on the left side, voluminous, of a purulent character, and accompanied by pneumothorax. None of these characteristics, however, is essential. Two groups of cases may be distinguished: In the first, the pulsation is perceived without the existence of any external tumor. In the second, there is a so-called empyema necessitatis; in other words, the purulent exudate has perforated the chest wall with the formation of a subcutaneous abscess. The perforation in these cases is often signalized, as first noted by Dieulafoy, by the occurrence of intense pain in the posteroinferior part of the thorax, which pain is increased by cough and by palpation of the region affected. A tumefaction rapidly appears and develops into a small circumscribed or into a large diffuse tumor. The peculiar character of this

tumor is its pulsation which in its sudden systolic character resembles that of an aneurysm, but in which a thrill is absent. There is some difference of opinion as to the expansile nature of the pulsation. The mass is frequently reducible, at least in part. On auscultation no murmur is detected; this is a point of considerable importance in differentiating the condition from an aneurysm of the aorta. The primary cause of a pulsating pleurisy is tuberculosis or pneumonia. In the diagnosis, apart from the points of differentiation from aortic aneurysm already alluded to, in which differentiation the *x*-rays offer considerable aid, one must also bear in mind the possible occurrence of a pulsating cold abscess in the precordial region, of an extensive aneurysm of the descending portion of the arch of the aorta, or of an aneurysm coexisting with a pleural exudate. In the treatment incision and occasionally mere puncture are effective in the acute pneumonic cases, while in the chronic tuberculous cases puncture alone is the method to be employed.

As regards the origin of the pulsations most authors attribute these to the impact of the heart, while others have alluded to the possible rôle of the pulsations of the aorta, or even of the lung. The pleural contents are always under considerable tension. The thoracic wall is thickened and of diminished elasticity. From these facts one may readily conceive how the pulsations of the heart may be transmitted through the retracted lung and its surrounding exudate to the extrathoracic mass. Rummo was the first to demonstrate the mechanical factors in these cases. He showed by means of manometric studies that in the case of certain pleural exudates even without the presence of any external mass there is a pulsation. This endopleural pulse is synchronous with the movements of the heart. The *x*-rays reveal these pulsations unmistakably. On the basis of Rummo's original observations one may now classify the cases of pulsating pleurisy as follows: (1) those presenting an endopleural pulse without any visible external pulsation; (2) those in which an external pulsation may be detected although there is no extracostal purulent accumulation; and (3) cases of pulsating empyema necessitatis with a pulsating mass on the outside of the thorax.

IS BOVINE TUBERCULOSIS PROTECTIVE TO MAN?

Much difference of opinion exists with respect to the manner in which infants become infected with tuberculosis. German medical authorities, as a rule, ascribe to the human type of tubercle bacillus infection of both children and adults, while a large number of well-known British investigators are of the opinion that the bovine tubercle bacillus is responsible for perhaps most of the cases of tuberculosis which occur in various forms in the young. Statistics bearing on the matter appear so conflicting that the solution of the problem seems still a long way off. German figures lead to the conclusion that bovine tuberculosis is a negligible quantity so far as dangerous infection of infants is concerned, and British statistics, especially those from Edinburgh, are of quite an opposite character and seem to supply more or less conclusive evidence that bovine tuberculosis is a great menace to infant health and life.

At the British National Conference on Infant Mortality held recently in Liverpool, Dr. Clive Rivière read a paper on the subject in which he reviewed exhaustively the existing situation and advanced certain conclusions of a somewhat original nature, which will probably not altogether commend themselves to the majority of those who have made a study of tuberculosis in its relation to infant mortality. Rivière again propounded the question, which he asked a few months ago, as to whether bovine tuberculosis was not at the present time doing useful work in protecting the community against the more virulent variety of tubercle bacillus, the cause of phthisis and of most fatal forms of tuberculosis. In partial corroboration of this suggestion, it was pointed out that in Edinburgh, where bovine infection of infants and children was very common, the phthisis mortality was only one-third of that of Vienna, where bovine disease was rare. Indeed, according to Rivière, a similar incidence of bovine infection and low phthisis mortality might be claimed for Great Britain as a whole in comparison with other countries of Europe.

If Rivière's views are correct it is better that infants become infected with the bovine tubercule, for thus they acquire a considerable degree of immunity against the human type and mortality is consequently lessened. A logical suggestion would therefore be that it would be better to take measures to secure a mild bovine infection instead of leaving our children to risk a first encounter with the infinitely more virulent human organism. The speaker also laid great stress on the fact that no amount of precaution would protect young infants in tuberculous households and that they should be removed as soon as possible from such dangerous surroundings.

There is possibly some truth in Rivière's views, but the matter will require much more investigation ere they can be accepted in toto. Perhaps raw cow's milk may not be so dangerous as is generally supposed. On the other hand it certainly has been known to spread disease. Besides, there are many whose opinion carries weight who hold that the bovine tubercle is responsible for dangerous forms of tuberculosis in children, and it will be difficult to disprove this contention. Until several moot points have been absolutely cleared up, it will be wise to pasteurize milk and to take every precaution to prevent the spread of tuberculosis by that medium.

War and the Progress of Medical Science

It may be premature to attempt to prophesy the ultimate effects of the insane struggle in Europe upon the progress of medical science, but there can be no doubt that in Europe, where the torch of science has been carried high, the economic losses resulting from a long continued war would dim its radiance for many years to come. Attainment in science and in the liberal arts is favored by unre-

stricted leisure and freedom from the stresses and cares of daily life, and the dissipation of a country's resources cannot but react unfavorably in halting the onward march of science. In addition to the diminishing endowments for research which will presumably follow the war, there is another important factor that will hamper medical investigation. The mobilization of the large European armies must drain the laboratories and the clinics of their brilliant young workers, who as reservists, volunteers, or members of the Red Cross, will be added to the medical corps of the respective armies. On the other hand, these men, or such of them as survive, will return with an experience which may perhaps more than compensate for the interruption in the orderly prosecution of research; but even research is not altogether paralyzed by war. In addition to the surgeons attached to the armies in the field there are medical men detailed at headquarters or at the base of supplies who carry on important investigations in connection with the hospital work of the medical corps. During the Russo-Japanese war, while the Russian army was engaged in Manchuria, there were being carried on in the army headquarters at Moscow important bacteriological investigations as to the nature of so-called Manchurian typhus, and the story need not be retold of the wonderful achievements of the Japanese in camp sanitation. Even on the battlefield progress may be made, for tradition has it that it was there that Ambroise Paré flung aside the cautery to demonstrate the superiority of the ligature in the treatment of wounded arteries.

Arsenization in Yellow Fever.

During the yellow fever epidemic in New Orleans in the summer of 1905 there was for a time much said in the newspapers regarding the use of small doses of arsenic in the prophylaxis and treatment of that disease. A popular experiment on a large scale was made in response to a letter written by Dr. R. B. Leach to a citizen of that town and published in the *Times-Democrat* of August 3, in which he stated that a dose of 1 100 grain arsenous acid, taken at first three times a day and later once daily, would protect against yellow fever. The publication of this letter was beneficial to the drug trade at least, for it is stated that over 15,000,000 tablets of arsenous acid were sold in New Orleans within a little over three weeks. Whether the results were equally beneficial to the partaking public is a matter of dispute. Dr. White of the Public Health Service, who was in charge of the epidemic, was unable to find evidences of any preventive action, but Dr. Leach contended that it was the wholesale arsenization of the population of the city, rather than the anti-mosquito crusade, that put an end to the epidemic. There the matter rested and the material being exhausted there was no opportunity for further experimentation. Dr. Leach, however, is still convinced of the prophylactic value of arsenic and he has appealed to Congress, in a memorial presented by Senator Sheppard, to pass a resolution requesting the President to appoint a commission to visit communities where yellow fever is in evidence and therein to test the arsenization prophylaxis of yellow fever, so that its value may be proved or disproved incontrovertibly. The theory is based upon the principles of homeopathy, the "symptoms" of arsenic poisoning being similar to those of yellow fever. A year ago the American Institute of Homeopathy suggested to the American Medical Association that a trial be made by a joint committee of the doctrine of similars. The suggestion was courteously received, but we have not heard that it has ever led to any practical results. If Congress should adopt the resolution offered on behalf of Dr. Leach, it would be opportune to appoint one or more homeopathists on the yellow fever commission and thereby a beginning could be made of a joint test of the doctrine of Hahnemann as well as of the theory of Leach.

The Law Regarding Revocation of the Medical License.

Complaint is sometimes made in this city that the County Medical Society is not sufficiently active against quacks and particularly against lawbreakers in the ranks of the profession. One very good reason for this apparent laxity, especially as regards the latter class, is that the law officers of the society are not omniscient and often obtain the information necessary to proceed against an offender only by chance. Those who complain appear to be ignorant of the fact that they have the remedy in their own hands and that all that is necessary is for them to call the attention of the proper authorities to the offense in any particular instance. The license to practise medicine may be revoked in any of the following cases: A practitioner of medicine who (*a*) is guilty of any fraud or deceit in his practice, or who is guilty of a crime or misdemeanor, or who is guilty of any fraud or deceit by which he was admitted to practice; or (*b*) is an habitual drunkard or habitually addicted to the use of morphine, opium, cocaine, or other drugs having a similar effect; or (*c*) who undertakes or engages in any manner or by any ways or means whatsoever, to procure or perform any criminal abortion as the same is defined by section 80 of the penal law; or (*d*) who offers or undertakes by any manner or means to violate any of the provisions of section 1142 of the penal law. (This section provides punishment for those convicted of promulgating indecent articles or supplying others with means for the prevention of conception.) Proceedings for the revocation of a license are begun by filing written charges against the accused. The papers should be made out in duplicate, one copy to be filed with the Commissioner of Education, the other with the Secretary of the State Board of Medical Examiners, Education Building, Albany, N. Y. Charges may be preferred by any person.

News of the Week.

Decrease in Infant Deaths.—During the first week of August the number of deaths of infants under one year of age was 331, or 50 less than the number for the corresponding week of last year. The decrease occurred largely in Manhattan Borough.

Vital Statistics and War.—The Department of Health of New York has recently issued a compilation of statistics which "explain why the Kaiser is able to put so large an army of young fighters into the field, and perhaps also indicate why Germany preferred fighting now to postponing the conflict." In 1880, it is stated, Berlin had the highest birth rate of the large European cities, 40 births per 1,000 of population. This lead it held from 1880 until 1893, at which time London

took the lead. The following year the birth rates of both London and New York were larger than that of Berlin. "It is clear," says the *Bulletin* of the Department, "that the enormous birth rate between 1880 and 1893 still shows its effect in the present German army, for all of these individuals are now between 21 and 34 years old and therefore constitute the flower of the fighting force. With the decline in the birth rate, and especially since Berlin was passed by London in 1893, it must have been clear to the Kaiser that the prospects for a continuation of an overwhelmingly large army were becoming dimmed." In 1913, the birth rate of New York was 26 per 1,000 of population; of London, 23; of Berlin, 20; of Paris, 17; and of Brussels, 16.

Periodical Physical Examinations.—The Department of Health of New York City last May adopted a plan for the examination at regular intervals of employees of the Department, since it was believed that such examinations would promote the health of the employees, prevent the development of disease, and ultimately reduce the total number of absences from the department because of sickness. Although the examinations were officially instituted, they were entirely voluntary, and employees were permitted to choose as to whether they would submit to examination or not. At the same time they were assured that the records would be treated with strict professional reserve, and would not be used in any way to affect injuriously the efficiency ratings. The following report of the conditions found in the first 300 examinations has recently been made: Six errors of nutrition, based on decided variations from normal weight in proportion to height. Seven decided defects of hearing, and one instance of suppurating otitis. Six instances of uncorrected defects of vision. Ten instances of marked disorders of digestion, chiefly such as affect sedentary workers. Thirteen instances of defective teeth needing dental care. Fifteen minor defects of the tonsils, throat, and upper respiratory tract. Twenty instances of appreciable defects of heart action, among which appeared five needing particular precautions in regard to manner of living. Fourteen instances of pulmonary defect, of which three were healed lesions resulting from pulmonary tuberculosis; two were instances of early processes put under medical care; and the remainder were minor and temporary affections. Two instances of anemia needing care. Two cases of high blood pressure needing medical treatment or alteration in manner of living or personal habits, and associated therewith errors in kidney functions. The following minor variations from normal were found, which did not appear to affect the health of the individual: Palpable spleen, three cases; palpable kidney, one case; enlarged thyroid, one case; subacute skin affection, one case. Alimentary glycosuria was found in one case, but on re-examination had disappeared. A moderate albuminuria was found in a number of cases but not to an extent to indicate pathological conditions, except in the two cases above referred to which were associated with arterial hypertension. One severe disorder of the nervous system which should respond to appropriate medical treatment, was found. The department believes that examinations of this kind represent an instrument for good and should be generally used.

Personals.—Dr. ALEXIS CARREL of the Rockefeller Institute, New York, who has been spending the summer abroad, is reported to have offered his services as a surgeon to the French army, and to have gone to the front. Dr. Carrel is still a citizen of France, although he has carried on his work in the United States for nearly ten years.

Dr. JOSEPH A. BLAKE of this city is a member of the American Ambulance Corps recently organized in connection with the American Hospital in Paris.

Dr. A. I. RINGER, instructor in physiological chemistry in the University of Pennsylvania, Department of Medicine, has been advanced to the position of assistant professor of physiological chemistry in the University.

Dr. NATHAN S. YAWGER of Philadelphia has been appointed assistant neurologist at the Philadelphia General Hospital, in the service of Dr. William G. Spiller.

Call for Nurses.—The first call for enrolled Red Cross nurses to join the relief expedition which the American society is to send to Europe went out on August 15. It is planned to procure for this work as far as possible physicians and nurses who are native Americans, in order to make sure that none of them shall be in any way biased.

Plague in New Orleans.—Two additional cases of bubonic plague were discovered in New Orleans on August 13, making seventeen in all since the discovery of the first case on June 27.

James City County (Va.) Medical Society.—At a meeting in Williamsburg, Va., on August 8, this society was organized, the following officers being elected: *President*, Dr. David J. King of Williamsburg; *Vice-President*, Dr. John C. Cutler, Norge; *Secretary-Treasurer*, Dr. Susan A. Price, Williamsburg.

The National Medical Association.—The sixteenth annual meeting of this association will be held in Raleigh, N. C., August 25-27, 1914, under the presidency of Dr. A. M. Brown of Birmingham, Ala. The general secretary of the association is Dr. W. G. Alexander of Orange, N. J.

First District (Georgia) Medical Society.—At the mid-summer meeting held in Savannah on July 27, the following officers were elected for the ensuing year: *President*, Dr. Herman W. Hesse, Savannah; *Vice-presidents*, Dr. G. W. Elarbee, Daisy; and Dr. Wm. Walker Evans, Halcyon Dale; *Secretary-Treasurer*, Dr. Charles Usher, Savannah.

Obituary Notes. — Dr. ELMORE FERDINAND ARNOLD of New York, a graduate of the New York University Medical College in 1885, died at Londonderry, Vt., on August 11.

Dr. FREDERICK C. BEALS, of Salamanca, N. Y., a graduate of the University of Buffalo, Medical Department, in 1875, city physician of Salamanca, surgeon to the Salamanca Hospital, and a member of the New York State and Cattaraugus County Medical Societies, died at his home, after a long illness, on July 25, aged 62 years.

Dr. CHARLES THOMAS BUFFUM, of New York, a graduate of the College of Physicians and Surgeons, New York, in 1877, and for some time a member of the staff of the Department of Health of New York, died at the Presbyterian Hospital, New York, on July 28, aged 61 years.

Dr. HERBERT FORREST WILLIAMS of Philadelphia, a graduate of the Hahnemann Medical College and Hospital, Philadelphia, in 1896, died at his home, from pulmonary tuberculosis, on July 26, aged 42 years.

Correspondence.

THE NOTIFICATION OF VENEREAL DISEASE.

To the Editor of The Medical Record:

Sir:—A great many inquiries have been addressed to me since the publication of my article, "Should the Sanitary Control of Prostitution be Abandoned?" in your issue of June 13, asking what system I would advocate for reporting cases of venereal diseases to the health authorities. In order to satisfy these past, and possibly future, requests for information on this point, will you kindly grant me space in the columns of the Medical Record?

I would propose the enactment of a law requiring physicians to report, by number, every case of venereal disease to the health departments of their municipality and State. The physician is further required to inform the health department of the subsequent history of this case.

The procedure should be in more or less the following manner: The treatment should commence with handing the patient a brief circular, which he is to read and sign in duplicate, and which should remain provisionally in the record files of the physician. This circular contains information about the severity of the disease and the precautionary measures required to insure the patient's safety and that of others, and on the absolute necessity of continued medical observation and treatment till cured. It should contain at the end the assurance that as long as the patient remains under the eyes and in the hands of a recognized practitioner absolute secrecy will be guaranteed him; should he, however, disobey or stop treatment, the patient then becomes a menace to public health, and as such will be made known to the proper authorities by name and address.

The circular should contain the following information: (1) Whether treatment has been completed and cure effected. (2) Whether, still suffering from disease, patient has passed into the hands of other physicians, and whom. (3) If, still affected with disease, patient passed out of hands of first physician, subsequent steps unknown. (4) Whether case has given up treatment before having been cured. (5) If of fatal issue.

It is easily understood what steps are to be taken according to the patient's compliance with the conditions specified in the circular. Affirmative answers to 1 and 2 (which always have to be forwarded to the health authorities in order to enable them to register the complete history of every case number), will secure to the patient the privilege of the strictest discretion, like any other private patient, as to the nature of his ailment, but the same to 3 and 4 are immediately followed by a report of the case with name and address to the health authorities and accompanied by one of the signed circulars. The refractory patient receives a notice from the health department requiring an immediate response. This notice may simply state that paragraph 3 or 4 of the circular handed to, and signed by him, at the beginning of treatment, needs immediate attention. In either case, the information that the patient has put himself under the care of another reputable physician, whose name and verification of this fact must be furnished, frees from further trouble just as long as the regulations are respected. Should, however, no such action follow the notification, the patient is required to appear before the examining health official, and positive evidence of infection with venereal disease being found, is ordered to appear for treatment in the health department's free clinic for the treatment of venereal diseases, until cured.

The law must further provide that patients who do not obey these regulations shall be taken to a public hospital and kept there until cured. This premises the existence of a free municipal clinic for men and women for the treatment of venereal diseases and for a sufficient number of hospital beds to accommodate those who require hospital treatment, for either intractability or indigence, or in consequence of the severity of their illness. That institutions providing such care should be present in every community that advances any claim to the preservation of public health, is just as true as that in the vast majority of American communities, large, medium, and small, they are conspicuous by their absence.

Either special hours or special quarters of the free clinic should be reserved for the regular compulsory examination of prostitutes on lines fully defined in former papers,* which exhaustively illustrate and explain the necessity of that provision for the effectual struggle with the great spread of venereal diseases.

Julius Rosenstirn, M.D.

126 Stockton Street, San Francisco.

OUR LETTER FROM THE PHILIPPINES

(From Our Regular Correspondent.)

PUBLIC HEALTH LECTURES IN THE PROVINCES—ASCARIS LUMBRICOIDES IN THE COMMON GALLDUCT—THE PLAGUE—RAT-PROOFING ORDINANCE IN MANILA.

Manilla, P. I., June 29, 1914.

The Bureau of Health is meeting with a most hearty response from the public in the provinces on account of the public health lectures which are at present being given, in which moving pictures and lantern slides are used in order to illustrate health subjects. Illustrated health lectures have received much attention in the Philippines during the past three or four years, but the efforts were much handicapped because the apparatus for generating the electric current necessary to operate a suitable lantern was so heavy as not to be readily portable in the more remote districts. After several years of experimenting an apparatus has now been secured the total weight of which, including the dynamo, lantern, slides, and accessories, is only 361 kilos. It can be readily set up, and it is quite practicable to make one night stands with it. The attendance at the lectures is far beyond expectations. A curious incident in connection therewith is the fact that numerous requests have been received from the inhabitants of many towns to lengthen the lectures from one hour to two hours. On account of the steady increase in the number of typhoid cases, special stress is being laid upon this disease in the lectures.

A case recently came to autopsy in Manila which during life presented practically all of the symp-

*The Municipal Clinic of San Francisco, Medical Record, March 15, 1913; Transactions of the Fifteenth International Congress on Hygiene and Demography, Washington, D. C., Sept. 23-28, 1912. Our Nation's Health Endangered by Poisonous Infection Through the Social Malady; the Protective Work of the Municipal Clinic of San Francisco and Its Fight for Existence. Town Talk Publishing Company, San Francisco. Should the Sanitary Control of Prostitution Be Abandoned? Medical Record, June 13, 1914.

toms of acute gallduct obstruction. The post mortem showed that the common duct was obstructed by an ascaris lumbricoides.

A case of plague developed among the suspects of the S.S. Linan, which arrived in Manila from Amoy on June 13. This is the third ship which has conveyed human cases of plague to Manila during the past few weeks. Several weeks ago the naval authorities reported the presence of a plague infected rat at Olongapo. Investigation showed that the rat came from a lighter used in Olongapo Bay. An anti-rat campaign was immediately started, but so far no further plague infected rats have been found. It has been surmised that in view of the fact that some of the vessels at Olongapo have been on duty in China on the Yangtze-Kiang and West Rivers that they may have taken the infection aboard through rats which came from the shores of these rivers. Steps are now being taken to fumigate all the water craft at Olongapo and the anti-rat campaign is being extended from the Naval Station proper to the adjacent village.

Last week a case was sent in to the Philippine General Hospital as acute meningitis, which upon autopsy proved to be a case of septicemic plague.

The efforts of the Bureau of Health to have a rat-proofing ordinance passed by the Municipal Board have at last borne fruit and the following essential provisions have been enacted into law:

"Section 1. All buildings hereafter to be erected within the city of Manila shall be so designed, planned and constructed that they will not have hollow walls or partitions, hollow ceilings, hollow stairs, hollow floors, nor hollow columns or other hollow structural parts which may serve or tend to harbor, shelter, or provide access or entrance to, rats or other similar vermin. All walls, with the exception of solid wood framing and of partition walls not extending below the floor surface, shall be of concrete, brick, stone, mortar, or other material proof against the incursion of rats to a height of one meter from the ground and shall extend below the ground to a depth of at least twice the thickness of the wall. Nothing in this ordinance shall be construed to prohibit the construction of double concrete, masonry or steel walls, or hollow steel, iron or concrete columns, provided that no entrances to hollow spaces are allowed.

"Sec. 2. All buildings hereafter undergoing repairs to parts having hollow spaces shall be repaired in such a manner as to remove such hollow spaces as are reached by the repair work, provided the safety of the building permits such removal.

"Sec. 3. It shall be unlawful for any person to construct or to cause or undertake the construction of any building or part thereof, or to repair or to cause or undertake the repair of any building or part thereof, which construction or repair shall not be designed so as, or shall fail in any respect, to conform to any of the requirements of this ordinance.

"Every violation hereof by any person shall be punished by a fine not exceeding two hundred pesos, or by imprisonment not exceeding six months, or by both such fine and imprisonment, in the discretion of the court. The word 'person,' as used in this ordinance, shall be construed to import both the plural and the singular, as the case demands, and to include copartnerships or other commercial associations and corporations. When construing and enforcing the provisions of this ordinance, the act, omission, or failure of any officer, agent, or other person acting for or employed by any copartnership or other commercial association or corporation, within the scope of his employment or office, shall in every case be also deemed to be the act, omission, or failure of such copartnership, association or corporation, as well as that of the person."

CLINICAL CONGRESS OF SURGEONS OF NORTH AMERICA.

(From Our Special Correspondent.)

EVERY session of this congress was well attended, the large banqueting hall of the Hotel Cecil being filled each evening while the meetings, which took place in the Savoy Hotel at the same time, attracted almost as large an audience.

On the evening of July 28 three papers of considerable interest were read. The first paper discussed suture of the levator ani muscle in perineorrhaphy operations and was contributed by Dr. Henry Jellett, master of the Rotunda Hospital, Dublin. The following were Dr. Jellett's conclusions as to the value of this procedure: (1) Routine suture of the levator ani was an essential part of perineorrhaphy. (2) Routine suture was always practicable, except when the muscle was wanting owing to atrophy after injury. Such absence was very rare, and when it occurred it was impossible to reconstitute the perineum satisfactorily. (3) The exposure and suture of the levator ani were neither difficult nor dangerous.

The next paper read was one of the best of the meeting. It was by Mr. Robert Jones of Liverpool and was entitled "Internal Derangements of the Knee." Mr. Jones said in part that he had chosen the subject because comparatively so little had been written about it in America, and this had always been a matter of great surprise to him, for American games like English games were rough, and England knew to her cost that American youth were very skilled and very strenuous. He had been credibly informed that the anatomy of their knee-joints differed but little from the English, and he was forced to conclude either that their cartilages were more securely placed than the English, or, which was most unlikely, that the condition was not so generally recognized as it should be. It was pointed out that by far the most common derangement of the knee was injury to the internal semilunar cartilage. It occurred eight times more often than did injury to the external meniscus. The internal cartilage was more firmly fixed and was not allowed the give-and-take movement vouchsafed the external, and in addition it bore a greater strain during the normal movements of the joint, becoming thinned and frayed along its inner margin. The most constant symptom of a displaced or fractured semilunar was a sudden inability to extend the knee. The most frequent cause of the displacement or fracture was strain thrown on the internal lateral ligament while the knee was flexed and the tibia rotated outward. In rare instances Jones had known a displacement occur while the knee was fully extended. The force necessary to cause the derangement in a first injury was usually severe, and the pain was acute. If an injured semilunar was rationally treated after its initial displacement it stood a good chance of being completely cured. The first displacement was not often accompanied by a degenerative change; reduction, however, must be absolute. All movements of the cartilage must be prevented until union of the torn structures was

complete, and no lateral strain must be allowed until the lateral ligament, so often injured, had had time to effect a recovery. There were many ways of reducing a cartilage, but, if no anesthetic were used, the speaker had always thought it wise to summon the assistance of the patient himself. The knee was first fully flexed and rotated inward, and the patient was then told at the count of three to forcibly extend his own knee while he was assisted by pressure from above. Jones had often in this way reduced displacements of several weeks' duration and the reduction could usually be felt by the surgeon. If the displacement were corrected the patient usually knew definitely and at once, and the surgeon if wise would abide by the verdict. The knee should remain fully extended after reduction in all recent displacements. If a knee did not voluntarily remain completely extended the displacement was not corrected. Such a joint with a clear history of semilunar injury and strained or ruptured internal lateral ligament should be treated by complete rest in full extension for four or five weeks and so long as the effusion lasted the patient should be recumbent. Prolonged effusion relaxed by elongation all the protective structures of the joint; and aspiration should be done if absorption were retarded. Massage could be employed while the knee was being tested in extension, and it was still more valuable to encourage the patient to practice contracting his quadriceps without flexing the joint. When the patient was up his internal lateral ligament should be guarded from strain during walking by directing him to walk with the toe slightly turned and his foot inverted. This was made easy by raising the heel of the shoe a third of an inch on the inner side to deviate body weight from the inner to the outer lateral ligament, just as would be done in an early case of knock knee. As cases were generally seen after the acute symptoms had subsided or when several recurrences had taken place, the history, which was usually definite enough, must be depended upon. Locking of the knee was the most definite and reliable symptom, and unless it occurred an element of doubt must always remain. Occasionally it was impossible to diagnose correctly without operation. Among the unexpected findings which operation had revealed were fringes and lipomata and pedunculated semi-detached bodies and Jones had had sometimes even to close his wound without having remedied any defect. The various symptoms of recurrent cases were then detailed and the statement made that operation was never performed immediately after the first displacement as so large a proportion of cases got well under appropriate treatment, nor was operation encouraged in cases where the recurrent trouble was painless and was never followed by effusion in the joint. Operation was strongly advocated where the recurrence was sometimes followed by effusion in the joint and it was encouraged in all recurrent cases where a strenuous active life was a means of livelihood or a physical necessity. Operation was a positive necessity in the case of men who worked among moving machinery or stood in positions where a yielding knee might mean disaster. An argument in favor of operation was the occurrence of tubercle and so-called rheumatoid trouble as a direct result of the irritation of a displaced cartilage.

If operation were decided upon Jones preferred to do so with the knee flexed to right angles, so that it need not be further flexed during the operation. He had a very real dread of accidental infection of the knee joint, for it might mean the loss of the limb. Further he considered a knee which had been the seat of trauma as very susceptible to infection, and was therefore careful not to operate during the presence of effusion nor to move it during operation for fear of the ingress of air or dust. The most convenient way was to have the limb hanging in flexion over the end of the operating table. Minute details of the operative procedure followed by Jones were then entered into and the paper was concluded by the exhibition of slides demonstrating the condition of joints of patients upon whom operation had been performed for various joint derangements.

In the discussion which ensued Mr. A. H. Tubby of London said that he decided to operate on following grounds: (1) Where the patient was unable to give the necessary time and had not the means to afford the apparatus required for mechanical treatment. (2) Where the patient was unable to obtain his livelihood shackled by a splint. (3) In the case of those who went up ladders, worked on scaffolds, or among machinery, where a sudden and unexpected fall might be fatal. (4) Where a support had been faithfully tried and had failed. In every case of operation its risks and results should be explained to the patient. He decided not to operate: (1) In any case of primary displacement. (2) Where a patient was content to wear an apparatus for a lengthened period. In his private practice Mr. Tubby operated on only 5 per cent. of his cases of internal derangement of the knee joint and laid special emphasis on the fact that the method of disinfecting the skin by means of acetone and iodide was insufficient when the knee was the site of infection.

Mr. Robert Milne of London said that the first thing to be done was to find out exactly what was wrong with the knee joint. He then gave his experience as to pathological conditions of the internal semilunar cartilage. He enumerated among such conditions longitudinal splitting of the cartilage, complete separation of the anterior end of the cartilage, a transverse tear and separation of the posterior end of the cartilage. The chief cause of displacement was rotation of the tibia inward on the femur, and the cardinal symptoms or "tripod" were three, viz., pain, effusion or locking of the joint.

The next paper read was by Professor Tuffier of Paris and dealt with transplantation of the ovaries. He said that he desired to present his experience in the transplanting of the ovaries after salpingitis and in case of fibroids of the uterus. In recent years he had done 204 such transplantations. In the hetero grafting of these organs, that is, transplanting from one subject to another, there had been 24 operations, and they were not successful. There had not been a single good result in an operation of this kind. The ovary had decreased in size, but he thought that with improvement in technique the operation might be performed successfully. Now the various elements of the body were attacked by the macrocytes. When we were able to find some chemical substance to protect the grafted organ the operation might be done. The other form of operation was autografting, that is, the grafting of the ovary from the woman's own body. Professor Tuffier had done this 145 times. After hysterectomy the implanation of one or two ovaries would overcome the symptoms of the change of life. In such cases the graft took and there was no change in the patient's after condition. He had removed the uterus and the salpinx from one or two sides and had then grafted

the ovary deep in the fatty tissues in 65 cases. This procedure had been shown to give great relief to the patient after salpingectomy, when the ovary was grafted near the uterus or in some other tissue. With regard to technique in chronic salpingitis the abdomen was opened, the ovary and tubes were held in the finger, the pedicle cut, the ovary taken in sterilized forceps and imbedded deep in the fatty abdominal tissue. After this operative measure when the broad ligament was normal the abdomen was closed. If in such an operation the ovary appeared septic it was dipped in iodine. The after results of this sterilization with iodine were that the ovary did not functionate and the patient did not menstruate for a considerable time. In these cases the ovary appeared nodular and lay dormant for three to four months, it was tender, the patient had symptoms of change of life, but after the sixth month the ovary increased in size and menstruation reappeared. The operation presented was not especially dangerous and he had never lost a patient as a result of its performance.

In thirty-four cases of grafting after hysterectomy thirty-two patients had normal periods. The other two cases were septic cases. In twenty-eight cases of grafting of both ovaries nineteen patients had regular menstruation, but after forty years of age the grafting had little or no effect. The question might possibly be raised as to whether the renewed menstruation could be due to portion of the gland that had been left in at the time of operation. Such a portion had not been found to produce function and if the ovary were grafted the ovary produced function soon after grafting. Professor Tuffier thought that ovulation and internal secretion of the ovary were not so important as had been believed. His experience had led him to formulate a new theory of the function of menstruation. He was of the opinion that every month the female organism secreted internally a chemical substance which was sufficient to act on the ovary. This chemical substance was eliminated by the menstrual flow and if it was retained by the body it caused an autointoxication. He had been able to produce menstruation by infection of defibrinated blood from a female about to menstruate into a female in whom the menses were suppressed. A sufficient dose of this serum had caused menstruation in patients who had not menstruated for two years after confinement. The flow appeared in from two to six days.

Resection of the uterus might be done without causing the symptoms of change of life. How much of the uterus might be taken in such conditions it was impossible to say, but according to his experience one-third of that organ might be safely removed. In cases of adhesions between ovaries and pelvis this operation was not so satisfactory. It was especially helpful in the case of young and nervous patients with excessive thyroid secretion.

1. The Problem of Infection in Tuberculous Families. J. B Hawes.
2. Something about Summer Diarrheas. I. D. Steinhardt.
3. The Modern Treatment of Inebriety. I. H. Neff.
4. Occupation Therapy in Organic Diseases. H. J. Hall.
5. A New Method of Treatment of Chronic Dacryocystitis. C. M. Cobb.

1. The Problem of Infection in Tuberculous Families.—J. B. Hawes states that tuberculous infection takes place chiefly in childhood years in the intimate contact of family life. There are three classes of consumptives who are the chief sources of family infection—the unknown case, the known case treated in his own home, and the returned sanatorium or hospital patient. The last class of returned sanatorium patients is the most important one and best repays one's efforts. The responsibility of the State towards its patients does not end when the patient is discharged, nor does the responsibility of the municipality end when the patient leaves for a State sanatorium. Co-operation between State and local forces must be constantly striven for. Tuberculosis is primarily a local problem. The State may well direct and advise, but not replace local work. The results obtained in Massachusetts as based on 600 discharged patients show that much can be accomplished in preventing family infection.

3. The Modern Treatment of Inebriety.—I. H. Neff outlines the following scheme which represents the system adopted by Massachusetts in the treatment of inebriety: (1) A State hospital for inebriates developed on the colony plan with a sufficiently ample and flexible equipment for the different types and grades of cases of habitual drunkenness. (2) An out-patient department with broad and well-defined duties. (3) Detention hospitals serving as adjunct institutions to the central hospital. These hospitals are to be situated in the cities and towns of the commonwealth. The hospital need not be especially built for the purpose, but should have special features for the care and treatment of acute alcoholism. Briefly defined, the purpose of these hospitals would be as follows: (a) For the treatment of delirium tremens. (b) To serve as an observation and receiving ward for the parent hospital. (c) To provide a clinic for incipient cases of inebriety. (d) To serve as sub-offices for the out-patient department of the main hospital. (e) To provide medical officers to visit prisons, to examine cases arrested for drunkenness, and to determine their fitness for treatment of the hospital.

4. Occupation Therapy in Organic Diseases.—H. J. Hall states that it has come to be a well-recognized fact that occupation of the body and mind is indispensable in the treatment of the functional nervous diseases. So far it has not been made clear enough, however, that the organic diseases, the chronic, partly disabling conditions may be made more bearable by the use of work especially adapted to the limitations of the individual. The symptoms of chronic spinal disease, for instance, are depressing in the extreme. A most evident and trying thing in the spinal cases may be incoordination in walking. For a good many years the Fränkel exercises have been used to improve the gait of the ataxic. There is no well-regulated nerve clinic or sanatorium without the familiar footsteps on the floor. But people get very tired of following in those footsteps, which seem to lead no whither. Many a man idle throughout a prolonged illness of this kind might be wonderfully developed if he could get in touch with the world through work. The author cites the case of a woman, apparently doomed to progressive disease of the spinal cord. With great difficulty she was persuaded to undertake hand weaving, a process which properly done requires very careful coordination of foot, hand, and eye. Before she knew it she was interested, and in a few weeks' time she had acquired the necessary skill which involves finding and correctly using from two to six foot pedals besides the dextrous throwing of a shuttle at the right time. The training thus received, together with the elation of accomplishment, raised this woman from the ranks of the hopeless and despondent to another kind of life altogether.

It is easy to understand what a boon to the poorer classes would be the teaching of adequate trades which could be carried out in the homes or in hospital workshops. There are many cases of progressive blindness in people along in years, or even in the middle life. If, while the blindness is coming on, a trade could be acquired it would mean pleasure and profit. Some of the chronic arthritis cases given up as hopeless yield to cleverly adapted work. Perhaps the most striking and inspiring work is being done in some of the hospitals for the insane. At Gardner, Mass., for instance, the State colony, with its 1,200 patients, keeps practically everybody at work. Under the direction of skilled people the patients for several years have made all their own clothing, the woolen part of which is manufactured from beginning to end, from the raising of the sheep through the processes of carding, spinning, and weaving, to the cutting and sewing of the garment ready for wear. This colony also raises all its food supplies, reclaims land, makes roads, and builds new dormitories. This is a most refreshing change from the days when the insane were almost universally kept in idleness and restraint.

8. Frederick Forchheimer. O. Juettner.

1. Lane's Complex and Senility.—I. L. Nascher believes that every one of the seventeen symptoms of autointoxication presented by Lane appears as a physiological manifestation of senescence or as a pathological condition to which the aged are especially susceptible. If one accepts Lane's statement that these symptoms are due to autointoxication, and to nothing else, then one must accept the autointoxication theory of senescence. Lane says these symptoms are so due in most cases; of but few does he say they may be or appear to be. As applied to the aged, few are clearly due to autointoxication. Autointoxication from intestinal stasis or from constipation due to lessened peristaltic activity undoubtedly plays a contributing part in the process of senescence. The aged are usually constipated, and indican is generally found in the urine, and yet one occasionally finds aged individuals who have never taken a laxative, who have no indicanuria, none of the symptoms one usually finds associated with autointoxication, yet who present early marked signs of senility. The secondary results of autointoxication, according to Lane, include greater susceptibility to infections, yet the aged are more resistant to infections, and some of the infectious diseases of early life rarely or never occur in the aged. Kinks and adventitious bands and membranes are frequently found in the aged without producing symptoms of stasis; ptoses of the abdominal viscera are the rule; and chronic constipation, with delayed passage of feces through the intestines due to diminished peristalsis, is usual. This last should produce the same results as stasis from gravity or kinks, but they do not follow. One must therefore assume that Lane's symptom complex does not hold good in the aged or else that Lane has accepted the autointoxication theory of senescence, and ascribes the various senile changes to autointoxication. This theory is not accepted as the basic cause of senescence.

7. Pathology of Syphilis.—H. J. Nichols notes that in syphilis the spirochetes localize during the early septicemia and probably do not localize in the later stages. All strains probably localize indifferently in certain organs. In addition certain strains probably have an especial localizing power. Various strains of *Treponema pallidum* exist which differ in pathogenic properties. These strains are probably permanent variations. A strain isolated from the nervous system has shown a marked power of generalization in the rabbit. Early localization in the testicle has been demonstrated experimentally, and the determination of a latent infection may be feasible as a clinical procedure. An active lesion in one part of the body tends to inhibit the development of potential lesions in other parts of the body.

9. Drug Absorption.—R. A. Hatcher and C. Eggleston determined the ratios of absorption from the four common channels of administration of drugs in five mammals, and recorded certain observations with regard to the ratios of absorption in man. The drugs used included representatives of several different chemical classes, such as alkaloids, glucosides, neutral principles, etc. Each drug is a law unto itself with respect to the ratio of absorption from the different channels of administration in any animal. In general, the subcutaneous and oral doses lie nearer to the intravenous dose in the cat and dog than in the rodents. The guinea pig in general seems far more resistant to the absorption of most vegetable drugs from the alimentary canal than is the rabbit, and vastly more so than are the cat and dog. Certain drugs, very soluble in water, are absorbed slowly, or occasionally not at all, from the gastrointestinal tract, this being especially marked in the case of the white rat and the guinea pig. Certain vegetable drugs, insoluble in water, are absorbed readily

from the alimentary canals of the cat and dog, and relatively so from the rat and guinea pig. No rule can be formulated for the calculation of the appropriate dose by one mode of administration from the dose by any other mode of administration. Such determination can be made only by experiment.

11. **Pituitary Extract.**—G. B. Roth calls attention to the wide variability that exists in the activity of commercial pituitary extracts. The use of beta-imidazolylethylamine hydrochloride in 1:20,000,000 dilution is suggested as a standard for use on the isolated uterus of the virgin guinea pig. The blood pressure method shows a wider range of variability than does the isolated uterus method for the comparison of the relative activity of the pituitary extracts and is not applicable to all preparations.

Ereuthophobia (Erythrophobia).—Bernhardt implies by this term morbid blushing, or the fear of blushing. Letters are quoted from a patient in which he complains that fear of blushing thwarts all his efforts to make a living and causes him to think of suicide. Aronsohn, one of the authorities on this phenomenon, who has seen many cases, pronounces it an independent affection. It has some connection with sexual life, as it occurs in onanists and the impotent. The author does not accept the sexual as the sole causal element, and insists that a neurasthenic component is present. Von Bechterew, who records himself as advocating the sexual nature of the phobia, mentions a neurasthenic inheritance. Friedlander regards the phenomenon as a mere symptom of neurasthenia. The victims naturally betray this fear in the presence of others. They have the obsession that some one will recognize by their look that they have at one time or another committed some immoral or unjust act. Naturally the vasomotor system must be extraordinarily excitable. Alcohol is able to overcome this state, although the patients have been found prone to abuse the remedy. Ever since Casper first described this condition (in 1846) the suicidal tendency has been remarked in certain cases. Imperative concepts were noted in the author's case.

Successful Removal of a Tumor of the Brain.—Alexander and Unger report that a young man had an attack of nocturnal epilepsy after alcoholic abuse. Other attacks succeeded and were recognized as examples of typical epilepsy, beginning, however, in the left side, the facial muscles being first involved. Diagnosis: pseudo-Jacksonian epilepsy; interned at Wuhlgarten as a genuine epileptic; about two years later, while still in that institution, he developed the syndrome of brain tumor. The convulsions were held to be due to irritation of the central convolution, as a result of the presence of a tumor in the white matter beneath the latter, which in its outward progress had probably destroyed the cortex at this point. The diagnosis was confirmed by the *x*-ray. The evidence showed that the mass had been growing for at least four years up to the time of operation. The tumor extended from the cortex to the lateral ventricle. It was extirpated under local anesthesia. The pressure symptoms were relieved and were replaced by certain motor and sensory disturbances due to the operation. A severe epileptic seizure occurred about two weeks later. The prognosis is good concerning recurrence because the growth had been encapsulated. The possibility of a scar epilepsy must be borne in mind, in addition to the genuine epilepsy.

Early Diagnosis of Pulmonary Tuberculosis.—Stern, in a joint review of this subject, gives some practical points as follows: Early diagnosis comprises recognition of tuberculosis of the bronchial glands by means of a combination of subjective and objective symptoms, including anemia, dyspeptic disturbances and diarrhea stools; in the circulatory system we see tachycardia and paroxysmal tachycardia, while the cardiac dullness is slightly amplified to the right. Pains in the shoulder region and abdomen suggest a tuberculous pleuritis. Of especial significance is the laryngeal symptom—paresis of the vocal cord on the side corresponding to the affected lung, with mild chronic laryngitis. Poor development of the muscles on the affected side often coexists and is not a consequence, but rather a predisposing cause, of the lesions. The pupil on the affected side is often more dilated and reacts more slowly to light than does its fellow.

Chronic Gastrointestinal Indigestion, Colitis Gravis, and Hepatic Cirrhosis.—Schütz describes this syndrome, which has been recognized for some years, and gives four personal cases in a few words. All patients had severe colitis, as shown by the escape of pus and blood by the rectum. It was necessary to exclude tuberculosis, dysentery, paratyphus, and typhoid. There was no peritonitis. In all four cases there was pronounced evidence of indigestion in the small intestine. The author concluded that the indigestion was the primary affection and the colitis secondary; in other words, intestinal insufficiency was somehow responsible for the severe inflammation of the large bowel. The small bowel had at the same time become highly irritable. As a result of these conditions it had harbored a pathogenic flora, which had set up abnormal putrefaction and fermentation, the products of which had proved irritable. In all probability the bacillus coli had become so virulent as to set up colitis. Hepatic cirrhosis is mentioned in one case only—an autopsy case in an infant, which in the absence of an alcoholic history shows how the intestinal lesions are able to cause this lesion.

Cholin Borate in Surgical Tuberculosis.—Baisch gives his experience with this salt in Wilms' clinic, Heidelberg. It has already been employed under a certain trademark name in carcinoma upon the theory that cholin can imitate the action of the *x*-rays. The latter are held by Werner to produce their characteristic action by breaking up the lecithin in the tissues and setting free cholin. The latter was found to be too toxic for use, and after considerable experimentation the borate was found to be an active salt and nontoxic. In 1909 Deycke and Much reported that cholin and neurin were able to dissolve tubercle bacilli *in vivo* and *in vitro*, thus giving an added indication for its use. The usual solvent is physiological salt solution. The physiological action of cholin when given in high dosage is that of a vasodilator. The face is flushed, there is visible pulsation of the arteries of the arm, a feeling of heat, increased secretion of tears, and sweat and vertigo. Cholin injections may be used simultaneously or alternately with the *x*-rays in the treatment. The full technique of injections is too long to be reproduced here. The drug, however, may be injected in the buttock or subcutaneously—not apparently in the tuberculous tissues. Cholin is said to affect the blood picture favorably. Of twenty-six cases treated the author noted no untoward effects. Care must be taken that the injections are neither too strong nor too often repeated, as should the pharmacological syndrome develop the vertigo indicates the danger point, since it may be at once followed by serious collapse.

July 16, 1914.

Relationship Between Flatfoot and Tuberculosis of the Foot.—Syring concludes that flatfoot, especially when unilateral, and with added evidence of a trauma, must be watched carefully for the possible development of local tuberculosis. We know that in tarsal tuberculosis the subjective and objective symptoms of flatfoot are often simulated; and in particular, when the disease is seated in the talo-navicular articulation the imitation may be perfect. But tuberculosis of the ankle joint may also simulate flatfoot at its inception. The danger of confusion between essential flatfoot and flatfoot as an early symptom of tuberculosis should not be underestimated. That such confusion does frequently occur is undoubted. In Garre's clinic 10 per cent. of all cases of foot tuberculosis were first diagnosticated as flatfoot. Upon suspicion of tuberculosis the foot must be kept in a rest position for some weeks and frequent *x*-ray examinations practised.

Treatment of Mammary Cancer in Mice by X-Rays and Chemotherapy.—Pentimalli agrees with von Wassermann that this growth is even more resistant to gamma rays than human cancer. So much more so in fact that mouse cancer can hardly be used as a control of the former. Even mouse cancer pulp in Ringers' solution gives negative results to the strongest raying. Chemotherapeutic experiments with selenium combinations and numerous other preparations of the same nature of reputed merit have given not a single unequivocal positive result. The success of others in this field must be explained by insufficient study of the histology of the growths after treatment, or by the fact that the tumors were not in their natural state, as a result of previous treatment, necrosis, etc.

Defect Symptoms After Affections of the Central Nervous System, Etc.—Rothmann sums up a long study of this subject by stating that these phenomena follow the phylogenetic law, according to which the phylogenetically old functions become defective with much greater difficulty than the phylogenetically young and undergo regeneration with much greater rapidity. This restitution can come about in various ways, the most important being the reappearance of independent functions of the phylogenetically old centers of the lower portion of the brain after defect of the higher nerve centers. The socalled practice or exercise therapy will hasten and perfect the restitution.

An Early Symptom of Pernicious Anemia—Soreness of the Tongue and Palate.—Stern, after stating his belief that pernicious anemia need not be a disease of one causation, calls attention to the fact that we know little of its initial symptoms. Anemia is certainly not one of these, nor are there any symptoms which suggest pernicious anemia. By the time anemia is in evidence the disease is far advanced. In other words, we have to deal with a secondary anemia. Of all early symptoms a periodical soreness of the tongue, gums, and palate is the most dependable. That no importance has been attached to it is because it has been noted heretofore only as a symptom of the fully developed disease. It was not until 1912 that Schaumann announced its existence as a forerunner of the anemia proper. A year later Zabel mentions burning of the tongue as an early symptom of the disease. The author has seen two, possibly three, cases of the buccal symptoms. In the first, owing to failure of nutrition and gastric disturbances, cancer of the stomach was suspected. Patient complained greatly of attacks of soreness of the tongue and gums which lasted a few days. These occurred at times when the general and gastric disturbances showed exacerbation. There was a diffuse redness of the anterior and lateral portions of the tongue and ecchymoses of the (toothless) gums. The true diagnosis was eventually made by the blood pictures. In the second case cancer of the stomach was also suspected. The entire mouth felt sore and hot, especially the tongue. This patient improved so much under treatment that the buccal symptoms vanished. The author advances no rationale to explain the mouth symptoms. He does not refer to the soreness of the palate which is sometimes seen after eructations and vomiting of acid gastric contents. As a rule the latter show a diminution of acidity in pernicious anemia.

Treatment of Diarrhea by Anesthetization of the Stomach.—Henius, basing his views upon Fuld's doctrine of a gastrocolic reflex, which he holds to be responsible for certain diarrheas, seeks to put the idea into practice. Many diarrheas are, as is well known, gastrogenic. Thus a meal taken with an irritable stomach is often promptly followed by a liquid movement. Much chronic or subacute diarrhea is of this origin. The prolonged action of mild laxatives seen in certain individuals may have a similar explanation. The ability of castor oil to put a stop to some of these cases is due, doubtless, to its soothing action. In these gastrogenic diarrheas a bland diet is of course the first requisite. Next in order comes the mild anesthetization of the stomach. Fuld at first made use of ten drops of a 3 per cent. solution of cocaine. Afterward synergists were added—menthol and a little soda. So far so good. The preparation, with possible additions, has, however, been placed on the market under a trade name.

Case of Athetoid Movements in Both Hands.—T. R. Whipham reports the case of a girl, aged four and a half years, who had never been able to hold anything properly in either hand owing to athetoid movements (alternating pronation and supination, together with flexion of the forearm), which became more marked when objects were grasped. She seemed a fairly bright child, but had not begun to walk until she was 3½ years old, though she is said to have cut her teeth and to have talked early. She was the first child of her parents, and was born at full term after a difficult labor lasting two days, at the end of which forceps were employed under an anesthetic. Immediately after birth she had to be revived by means of artificial respiration and brandy, and she is said not to have cried for the first two days. Marks from the instrument were present for a time on both sides of the face, and at the back of the head. The condition was probably due to injury sustained at the time of birth.—*Proceedings of the Rayol Society of Medicine.*

Veronal in Delirium Tremens.—Schneider takes part with others in an impromptu discussion on the medicinal treatment of the disease. Having been accused by implication of denying any virtue to this remedy, he states that he has never denied the benefit of very large doses of veronal, which produce more or less restfulness. He cannot convince himself, like von der Portens, that a veronal plan of treatment shortens the course of the disease or affects the mortality. In the so-called impending delirium there is no correspondence in results with the actual delirium in institutes. He includes the former, while the latter do not. Hydrotherapeutic procedures can be carried out only amid special surroundings, and when these are not available we have to depend on isolation and strong narcotics.—*Münchener medizinische Wochenschrift.*

Insurance Medicine.

SUGGESTIONS TO THE MEDICAL EXAMINER.

BY THE INSURANCE EDITOR.

HEREDITY.

Dawson and Spencer established the principle that every organism eventually more or less assumes the form of the class or order from which it sprang. This law of heredity, considerably modified, has been recognized as one of the fundamental truths involved in the selection of risks for life insurance, as there is abundant evidence that certain individuals display deviations from the normal, when the same or allied deviations appeared among their forebears. The inheritable characteristic may be transmitted directly to the child, or may become potent in some of the grandchildren after skipping a generation. The deviation, whether in form of a taint or of some desirable quality, may be accentuated or mitigated by the environment, advantages or disadvantages, and mode of life. From an insurance point of view, the physical organism, rather than the mental qualities, are of interest, but on looking into the subject of longevity, it is found that there is usually a succession of physically as well as mentally well-balanced progenitors, while, on the other hand, in the short-lived family there is apt to be a combined influence of parental taint, the predisposition from the parental side, supplemented and intensified by that from the maternal. The manifestation of a poor inheritance is not always the exact counterpart of that which appeared among the ancestors, certain diseases producing a tendency to other affections in succeeding generations.

After all is said, however, it must be acknowledged that many individuals defeat their baneful inheritances through the subjugation of their desires and passions for excesses of all kinds, by living in a favorable environment, by adopting modern precautions and treatment, and by following a suitable vocation. If all men could and would observe these precautions in a thorough and conscientious way, the question of family history might be almost disregarded, but these measures can rarely be fully carried out owing to the uncertainties of fortune, surroundings and domestic relations. Then, again, some men who have not lived prudently do reach advanced age, though their family histories are replete with evidences of disease and early deaths, the survival under such circumstances being attributed to a reversionary inheritance from some vigorous and robust ancestor. It is quite evident, then, that before the laws of mortality, as far as they are based upon the principle of heredity, can be intelligently applied, there should be a careful study in each individual case of the conditions which may modify, intensify or neutralize inherited tendencies.

The medical examiners will materially increase the value of their services by securing accurate family histories, with the favorable as well as unfavorable modifying factors, even though he finds that the different insurance offices are not harmonious in the treatment of the information furnished. There is no fixed or universal rule in regard to the influence of heredity, each office acting according to its own experience. In a general way it may be stated that some insurance men regard the bearing of family records as most important in connection with the selection of risks. Others prefer to be guided chiefly by the personal history and physical examination of the individual. Most men will agree, however, that the means between these extreme views may be considered as approximately correct and that the wise course to pursue is to study both the family and the individual characteristics. There is no doubt that family history no longer occupies its former important role in the selection of risks, owing to the benefits gained from a vigorous dissemination of ideas concerning prophylactic and curative methods and the importance of environment.

A discussion of the details of the subject would require the space of a volume. We may, however, refer briefly to the few following points which most commonly present themselves for consideration:

The latest investigations show that a family history strongly tainted with tuberculosis may be of small consequence after the age of 30, provided the occupation, habits and surroundings are favorable and the weight of the applicant is at or above the standard. A good weight overbalances such a family record to a marked degree. This brings up the point, on the other hand, that the estimates of liability to consumption in tainted family histories often underrate the risk, as they are apt to include only those dying from consumption, while it is generally conceded that there is a greater tendency to die of other diseases as well as from consumption among those who have that taint in their family. Greater weight and deeper study has naturally been accorded to tuberculosis than any other disease as an element in the family history. When, however, the record is marred with gout, rheumatism, apoplexy, insanity, diabetes, alcoholism, etc., and especially when these blemishes appear in both paternal and maternal branches, or when there are indications of short life from various causes, the home office authorities will scan the application closely. It is the consensus of opinion that inheritance of cancer is of a negligible quantity. If the case is at or near the borderline in other respects, the unfavorable family history often proves to be the crucial point on which the decision depends as to whether the applicant is rejected or offered a rated-up or endowment policy.

Mitral Stenosis.—In a discussion of the insurance aspects of this affection, at a meeting of the British Life Assurance Medical Officers' Association, Dr. Hector Mackenzie said that his own rule, at present, was this, that if he found well-marked mitral stenosis he recommended that the case should be declined. Mitral stenosis was generally, when one was able to diagnose it, a condition that had lasted a considerable time. It was generally an old standing valvular disease, and one knew that the duration of life in these cases was certainly diminished. The question really was one of diagnosis, for many cases were diagnosed mitral stenosis which were not such.

Otorrhea and Life Insurance.—At the meeting of the British Life Assurance Medical Officers' Association held on November 5, 1913, the subject of otorrhea in relation to life insurance was discussed. Dr. Ogier Ward pointed out that there was frequently an intimate connection between otorrhea and tuberculosis, and where there was a family history of tuberculosis those suffering from otorrhea should be declined. Dr. F. de Haviland Hall said that his custom in the past had been never to pass an applicant for insurance who had a discharge from the ear.

Book Reviews.

MANUAL OF MILITARY HYGIENE for the Military Services of the United States. By VALERY HAVARD, M.D., Colonel, Medical Corps, United States Army, Retired; Former President, Army Medical School. Published under the authority and with the approval of the Surgeon General U. S. Army. Second edition, thoroughly revised and greatly enlarged. Illustrated with seven plates and 251 engravings. New York: William Wood & Company, 1914.

IN the five years that have elapsed since the first edition of this excellent work much has been added to our store of knowledge in this field, and Havard has brought his book up to date in all completeness. The introduction constitutes in itself a valuable chapter, from which we quote a few pertinent axioms, upon which the practice of military hygiene must rest. "It is now recognized," says the author, "that the sanitary service of an army is not an impedimentum or necessary evil to be tolerated." "Hygienic measures are expensive but they will prove comparatively cheap if they prevent disease, for nothing is more expensive than a sick soldier." "All authority must necessarily be centered in the commanding officer; to divide it would lead to military chaos. Complete autonomy is no more possible or desirable in the medical than in any other staff department." The last axiom might well be digested by militia and volunteer officers, many of whom have curious misconceptions of their relations toward their commanders, and an exalted idea of their own authority.

As an evidence of the remarkable progress in military hygiene, Havard shows that there has been a steady decline in the death rate from 15 per mille in 1870 to 4.46 in 1910. The civil records in the United States give a corresponding decrease from 19.6 in 1890 to 15.0 in 1910. While the latter figures are encouraging in a way, they are hardly comparable to the marvellous decrease in our army. The mortality in the army in men from twenty to thirty years old is approximately but one-half that in the civilian population.

Under the heading "Infectious Diseases," typhoid fever is of paramount interest, not only on account of its old-time ravages, but particularly in view of the fact that we seem at last to have the mastery and to have eliminated it as a factor of importance. That this could have come about in the few years elapsed since the first edition of Havard's book seems incredible. While the rate had steadily declined since 1899, a sudden drop in the incidence of 3.03 and a mortality rate of .28 in 1909, to an incidence of .31 and a mortality of .03 in 1912 coincides with the introduction of antityphoid vaccination. In 1909-12 *no death* occurred in vaccinated soldiers.

The chapter on venereal diseases is important because of the high percentage of disability and discharge. For the entire army at home and abroad the total admission rate for venereal diseases was 185.3 and constant non-effective 10.14, the equivalent of 738 men. The rates in our navy are about the same, being 177 for 1911. Our improved means of diagnosis, the Wassermann reaction, and the discovery of the treponema will aid in the cure of syphilis by its earlier recognition. As medical officers rather agree that a large percentage of venereal diseases may be arrested by the prompt application of disinfectants, the use of the several prophylactic tubes is now common in both army and navy. Havard sees in the abolition of the canteen and its alternative, the existence of vile resorts in the proximity of garrisons, the "fons et origo" of much venereal disease and alcoholism. Alas! the matured judgment of veteran officers is of small weight contrasted with the misplaced enthusiasm of so-called prohibitionists and the timidity of weak-kneed Congressmen.

On the subject of "Recruiting," Havard contends that young men from country districts endure the hardships of a soldier better than those from cities. This is contrary to the opinion of many writers, and we have frequently heard veteran officers emphasize the reverse view. In the extremely interesting chapter on "Exercise", Havard states that during the last twenty years or more there has not been a serious injury among the cadets in the West Point gymnasium. He quite rightly condemns the methods of the annual exercise test, to which field officers are subjected, as it demands of men over fifty or even sixty years an identical physical strain (notwithstanding a lessened elasticity) which men in the 40's are called upon to undergo.

Clothing and uniform are discussed entertainingly from every standpoint. Touching upon the extensive experiments in the Philippines, directed toward the elimination of the actinic rays of the sun, it is shown that "the opacity of garment is as effective as color and that a black fabric, preferably silk, is altogether best for the purpose." Therefore, a black undershirt is suggested, such as the "solaro," olive drab outside and black inside. Attention is invited to the new haversack pack-carrier recently adopted by the War Department. The material used in its construction is olive drab cotton, bound with cotton webbing. It can be scrubbed when necessary and its advantages over any similar device in use in other armies are beyond question. An officer of the British Medical Corps pointed out this equipment to the writer in the museum of the Royal Army Medical College and expressed the hope that the English would adopt a similar pattern. Its virtues may be summed up briefly as follows: Its center of gravity corresponds nearly with that of the body; it hangs comfortably without constriction of the muscles, blood vessels, and nerves; it allows free expansion of the chest; there is no interference with the free use of arms and legs; it helps support the cartridge belt and its capacity is remarkable.

Space will not permit a detailed review of the chapters on barracks and camps, heating, lighting, and ventilation, which are replete with the latest statistics and comparisons of the most modern devices. We would commend to the militia officer those chapters dealing with camps, the disposal and destruction of excreta and waste, cooking and a chapter "General Sanitary Rules in the Field." There are also chapters on "Service in Warm Climates" and "Service in Cold Climates" which indicate to what extent the American resourcefulness must be tested, with a territory that embraces the Arctic Circle, the equatorial regions, and all the gradations of dry and moist climates that may lie between these extremes.

The book also includes a chapter on naval hygiene, which, though of necessity brief, gives some conception of the problems that face the naval medical officer; and also one on quarantine and its special application to the various infections. It is really remarkable what a storehouse of information lies between the covers of this book, and we see everywhere not only the mind of a deep student, but the mark of the highly trained veteran.

FORMULAIRE DE THERAPEUTIQUE CLINIQUE. Par le Dr. L. PRON, Membre de la Société de Thérapeutique. Avec la Collaboration du Dr. A. CANTONNET, Ophthalmologists des Hôpitaux de Paris (Hôpital Cochin). Deuxieme Édition, Réfondue et Augmentée. Price 6 francs. Paris: Librairie Maloine, 1914.

THIS handy volume of 544 pages comprises an alphabetical enumeration of various diseases with a brief description of their treatment, including a list of select prescriptions which may be used in each of those. There are separate sections on the treatment of diseases of the eyes, on diet lists in different conditions, on opotherapy, on serotherapy and vaccinotherapy, on poisoning and its treatment, on various laboratory examinations, on mineral waters, and on climatic resorts and sanatoria; and there is also a résumé of clinical phramacology. There is appended a table giving the ingredients of well-known ready-made mixtures.

MODERN SURGERY—GENERAL AND OPERATIVE. By JOHN CHALMERS DACOSTA, M.D., LL.D.; SAMUEL D. GROSS, Professor of Surgery, Jefferson Medical College, Philadelphia; Surgeon to the Jefferson Medical College Hospital; Surgeon to St. Joseph's Hospital, Philadelphia; Fellow of the American Surgical Association; Member of the American Philosophical Society; Membre de la Société International de Chirurgie; Member of the Medical Reserve Corps, U. S. Navy, etc. Seventh Edition, revised, enlarged, and reset, with 1,085 illustrations, some of them in colors. Price $6.00 net. Philadelphia and London: W. B. Saunders Company, 1914.

THIS, the seventh edition of Dr. DaCosta's Modern Surgery, has been brought well up to date. The author in a peculiarly felicitous and witty preface critically reviews, in a sense, his own book. He points out in what respects, he thinks, it is lacking and apologizes for its language being somewhat dogmatic and oracular because there was no room in the work for argument and discussion. This new edition contains considerably more matter than the preceding one, but by a slight increase in size of the page the additions have been made without adding greatly to the size or weight of the volume.

INFANT FEEDING. By CLIFFORD G. GRULEE, A.M., M.D.; Assistant Professor of Pediatrics at Rush Medical College (in affiliation with the University of Chicago); Chief of Pediatric Staff, Cook County Hospital; Attending Pediatrician to Cook County, Provident, and St. Bernard's Hospitals, and to the Home for Destitute Crippled Children, Chicago; Associate Pediatrician to the Presbyterian Hospital, Chicago. Illustrated; second edition, thoroughly revised; price $3.00 net. Philadelphia and London: W. B. Saunders Company, 1914.

THE subject of infant feeding has been greatly developed within the past few years, chiefly through the contributions made by German pediatricians. On the whole, the feeding of infants has been greatly simplified. In the present edition of this well-known work the author shows that he still accepts the teachings of the German school, which teachings have been accepted by many pediatricians in this country. This volume presents a most lucid account on the scientific feeding of infants.

Part I deals with the fundamental principles of infants' nutrition; Part II deals with the nourishment of the infant on the breast; Part III deals with artificial feeding, and Part IV discusses anomalies of nutrition and other conditions. The summary of the chapter headings may serve to indicate the wide scope of this volume. Part I contains chapters on special points in the anatomy of the gastrointestinal tract of the infant; the physiology of the gastrointestinal tract in the infant; absorption and metabolism; bacteriology of the gastrointestinal tract of the healthy infant; and attributes of the normal child. Part II includes chapters on the human breast and breast milk; technique of breast nursing of the normal infant; and nutritional disturbances in the breast-fed infant. Part III comprises chapters on foods used in artificial feeding; artificial feeding for the normal infant; general consideration of nutritional disturbances of the artificially fed infant; weight disturbance; dyspepsia; decomposition; intoxication; symptoms and their causes. Part IV consists of chapters on the premature infant; the exudative diathesis; the spasmophilic diathesis; the nervous infant; infant feeding in rickets; infantile scurvy; infant feeding in eczema; congenital pyloric stenosis and pylorospasm; and infant feeding in other diseases than those above mentioned.

The author's method of artificial feeding is a very simple one. It consists in the simple dilution of cow's milk with the addition of carbohydrates, preferably in the form of malt sugar and various starches. He believes that the intervals of feeding should not be any less than four hours and that the amount of food given should slightly exceed the stomach capacity for a child at a given age. The book is well written and should prove of eminent value to the student and general practitioner.

FESTSCHRIFT DEM EPPENDORFER KRANKENHAUSE ZUR Feier seines 25 jährigen Bestehens Gewidmet von früheren und jetzigen Ärzten der Anstalt. Unter Redaktion von Dr. BRAUER, Dr. SCHOTTMÜLLER und Dr. MUCH. Mit 20 tafeln und 22 abbildungen im Text. KLINISCHE BEITRÄGE: BEITRÄGE ZUR KLINIK DER INFEKTIONSKRANKHEITEN UND ZUR IMMUNITÄTSFORSCHUNG (MIT AUSSCHLUSS DER TUBERKULOSE). Herausgegeben von Professor Dr. L. BRAUER, ärztlichem Direktor des Allgemeinen Krankenhauses Hamburg-Eppendorf. Redaktion: für die Originale: Dr. H. SCHOTTMÜLLER (klinischer und bakteriologischer Teil) and Dr. H. MUCH (immunitätswissenschaftlicher Teil), beide am Allgemeinen Krankenhause Hamburg-Eppendorf. Für die Ergebnisse: Professor Dr. H. LÜDKE, in Würzburg. III Band, Heft ½. Price, per volume, 20 marks; single number, 15 marks. Würzburg: Curt Kabitzsch, 1914.

THIS festschrift has been compiled by the former and present workers of the Eppendorf Hospital in the celebration of the 25th anniversary of its foundation. The enumeration of the articles comprised in this volume may serve to give a fair conception of the important contributions that are now being made in the study of the infectious diseases. These articles are as follows: the relation between albuminous and lipoid antibodies and humoral and cellular reactions, by H. Much and Dr. Adam; hypersensitiveness, fever, and metabolism, by E. Leschke; plasma studies, by S. Starke and B. Hannes; experiments on dialysis and the Wassermann Reaction, by M. Fraenkel; experiments on the transformation of an organism by means of the treatment of bacteria-carriers, by A. Adam; protein end-products and the Wassermann reaction, by Dr. Mahlo; the effect of plant extracts soluble in alcohol and ether on bacteria, by O. Ganz; investigations on the prerequisites of the Wassermann reaction, by H. Emden and H. Much; investigations on the nature of the complement-binding reaction of the serum of patients having a tumor, by K. Hara; cataract operations with special reference to the prophylaxis of operative infectious inflammations, by A. H. Pagenstecher; acute hemorrhages following scarlatinal necroses and fatal bleeding from the ear, by E. Harnsen; the question of the rôle of the school in the causation of epidemics of scarlet fever and the measures thereby suggested from the public health aspect, by Dr. Voretzsch; the separation of the diphtheria membrane, by W. Meinshausen; clinical observations on typhus fever, by L. Brauer; a case of pure *Strongyloides stercoralis* infection with a fatal outcome, by E. Wilbrand; the phenol-serum treatment of pyogenic processes in gynecology and its experimental basis, by O. Geiger; the significance of the bacteriological examination of the blood in autogenous sepsis, by H. Schottmüller; a contribution to the pathology and diagnosis of pylephlebitis, by H. Schottmüller; the bactericidal power of human blood with reference to streptococci as an index of their virulence, by H. Schottmüller and W. Barfurth; the treatment of severe cases of scarlet fever with salvarsan or neosalvarsan, by F. Poensgen; the bacterial content of the fetus in abortions, by W. Barfurth; bacteriological examinations of the blood following curettage, by P. Theodor; staphylomycosis of the air-passages and lungs in childhood, by H. Schottmüller; the clinical picture of puerperal infection by the *Bacillus phlegmones emphysematosæ* (E. Fraenkel), by K. Bingold. This summary of the table of contents of this volume gives a fair idea of the extraordinary amount of work that is being done in the study of the problems of modern medicine. This volume is a mine of information and cannot fail to be of extreme interest to the clinician, alert on the frontiers of discovery.

COLLECTED STUDIES FROM THE BUREAU OF LABORATORIES, DEPARTMENT OF HEALTH, CITY OF NEW YORK. By Dr. WILLIAM H. PARK, Director. Vol. VII. 1912-1913.

THIS volume contains the results of the various studies carried on during 1912 and 1913 in the divisions of the bureaus of the laboratories of the New York Department of Health. These studies are classified under the following headings: applied therapy and preventive medicine; bacteriology, biochemistry, clinical cases with laboratory studies, food and drug chemistry, immunity, milk, clinical pathology, special pathology, physiology, and protozoology. Among the many valuable contributions to this volume may be mentioned the following: differential diagnosis and treatment of epidemic cerebrospinal meningitis, by Phebe L. DuBois; two cases treated with antistreptococcus serum, by M. Nicoll, Jr.; the dosage and methods of administering diphtheria antitoxin—an experimental and clinical study, by W. H. Park and G. P. Biggs; the relative importance of the bovine and human type of tubercle bacilli in the different forms of tuberculosis, by W. H. Park and C. Krumwiede, Jr.; on the presence of diphtheria and diphtheria-like organisms in scarlet fever patients, by Harriet L. Wilcox and Marian S. Taylor; is serum anaphylaxis a danger of sufficient importance to limit our use of protective sera in the treatment of prevention of disease, by W. H. Park; the frequency of *B. tuberculosis* in the market milk of New York City, by Marie Grund and Harriet L. Wilcox; tubercle bacilli in the blood, by Jane L. Berry; concerning the cultivation of the rabies organism, by Anna W. Williams, and the pancreatic ferments in infants, by A. F. Hess.

ZUR FRAGE DER ADERHAUTABHEBUNG NACH STAR- UND GLAUKOM-OPERATIONEN. Von Dr. BOIT, Stabsarzt. Kommandiert zur Universitäts-Augenklinik, Berlin. Price, $2.00. Halle, A. S.: Carl Marhold Verlagsbuchhandlung, 1914.

THE review of this very interesting and important compilation of cataract and glaucoma operations has been conducted in a comprehensive manner. After a careful analysis of the cases reported, twelve additional cases from the clinic of the University of Berlin are presented. The different theories of the cause of chorioidal detachment are given and discussed, and conclusions drawn. This timely and excellent review of the subject should be read by every ophthalmologist.

Society Reports.

BRITISH MEDICAL ASSOCIATION.

Eighty-second Annual Meeting, Held in Aberdeen, July 24-August 1, 1914.

(Special Report to the MEDICAL RECORD.)

(*Concluded from page 316.*)

SECTION OF OBSTETRICS AND GYNECOLOGY.

Wednesday, July 29—First Day.

Treatment of Fibromyomata.—Dr. ARCHIBALD DONALD of Manchester said that if expectant treatment had been tried it should be given up in all cases when symptoms developed; additional experience showed that the climacteric did not bring relief. Postclimacteric complications were the following: (1) Intramural fibroids might become submucous or polypoid and for the first time give rise to hemorrhage. (2) Diminishing size of the tumor might cause incarceration in the true helois. (3) Degenerations might occur. (4) Malignant changes might also take place. As regarded palliative treatment he had no faith in drugs and did not recommend curetting. Operative treatment: He performed vaginal removal only in cases where the cervix was open or the tumor was sloughing; in all others he operated by the abdominal route and he was of opinion that vaginal hysterectomy for fibroid should be abandoned. He performed myomectomy, when possible, in women of childbearing age, but would not do it for multiple tumors; in these it was a good plan to enucleate the tumors before doing hysterectomy. He preferred subtotal hysterectomy and thought that the risk of subsequent development of cancer in the stump was so rare as not to be worth consideration. Oophorectomy for fibroid was of no good and should not now be performed. Of operative cases he had had at the Royal Infirmary, Manchester, 101 cases with three deaths; at St. Mary's Hospital, 108 cases with three deaths; at the Nursing Home, 100 cases with one death. These included every case operated on. As regarded technique he clamped the broad ligament, having first tied the vessels after removing the uterus. He removed both ovaries in almost all cases. In many cases the ovaries, when left, degenerated, and in others they underwent cystic development or painful adhesions formed. He thought that subsequent symptoms depended entirely on the type of woman and not on whether the ovaries were removed. The principal dangers were thrombosis and embolism, and these would be almost entirely prevented by the strictest care in asepsis, using gloves and masks. These precautions were particularly necessary in anemic patients. "Team work" was also advantageous. He was opposed to *x*-ray treatment on the ground that mistakes in diagnosis were common in particularly hard masses, due to inflammation, and ovarian tumors adherent to the uterus might be mistaken for fibroids; ovarian and tubal disease might complicate fibroids; sarcoma, adenoma, or carcinoma might be present as well as degenerations of various kinds. It was by no means clear that there would be no further trouble with fibroids after bleeding had been stopped by means of the *x*-rays and he had reason to believe that if operations became necessary after *x*-ray treatment it would be more difficult.

Professor GAUSS of Freiburg sent a paper which was read in his absence by the secretary. He said that the results of *x*-ray therapy of fibroids were much superior to those of operation; moreover the mortality of operation was from 3 to 5 per cent. Surgeons avoided operating on anemic cases and these could be successfully treated by *x*-rays. The improvement lately was due to using hard rays in much stronger doses by the "cross fire" method and with aluminum filters. In 693 cases he had been successful in 95 per cent., and the results were steadily improving. As regards the technique he applied the rays over twelve areas in front and six posteriorly, each area being four to six cm. square and the aluminum filter three mm. thick. He considered that the treatment was contraindicated in submucous tumors which protruded from the uterus, and in cases where pressure symptoms were present.

Dr. HASTINGS TWEEDY of Dublin protested against treatment by *x*-rays. He said that if tumors were left alone 2 per cent. became malignant, and he advised that every case should be operated on when diagnosed. He disapproved the practice of removing the ovaries and said that if they were cystic he would resect the cystic part.

Dr. NIGEL STARK of Glasgow had seen death at the age of sixty-two from a sloughing fibroid. We all knew that cases of hemorrhage from metritis could be cured by electrical treatment; he had operated on 300 cases of fibroid with a mortality of 2 per cent.

Dr. MURDOCH CAMERON of Glasgow said that he did not use gloves. He recalled the Apostoli treatment and its disappearance from gynecology.

Sir JOHN BYERS of Belfast approved of gloves. He thought that some improvement in the results was due to much improved methods of anesthesia. He recalled cases in which the Apostoli treatment stopped hemorrhage, but the tumor still went on growing. He thought that some cases might well be left without operation.

Dr. KYNOCH of Dundee had sometimes removed the ovaries when he had found it impossible to get at the uterus owing to a very fat abdominal wall. He had abandoned myomectomy and thought it a good thing to leave some of the endometrium. He had seen the *x*-ray treatment in Freiburg and thought that there was something in it, he said, that every gynecological clinique in Germany had its department for the electrical treatment of fibroids and he advised withholding judgment on the matter for the present.

Dr. PHILIP WATSON of Toronto said that the cessation of menstruation in those cases was mainly due to the action of *x*-rays on the ovaries, and it was a strong argument against the treatment that the tumor was left and an artificial menopause was produced; he thought that the question of menopausal symptoms depended on the state of the ovaries at the time of operation and that where these were healthy the symptoms were more severe.

Dr. PURSLOW of Birmingham said that he usually performed supravaginal amputation of the uterus, but asked what should he done in cases complicated by lesion of the cervix, for, if this was left, the woman would complain of discharge after recovering from the operation, and he thought that the existence of severe erosion, with fibroid, indicated panhysterectomy.

Dr. BECKWITH WHITEHOUSE of Birmingham said that it was his practice always to remove the ovaries; he thought that if the ovaries were left some of the endometrium should also be left, as these two organs interacted.

Dr. HAULTAIN of Edinburgh, chairman of the Section, was not inclined to say that every woman with fibroid should be operated on. Those in whom symptoms were absent were usually sterile women under forty-five years of age and the question sometime arose whether operation should be done for the cure of the sterility; he would do myomectomy for this purpose if requested by the patient. In his experience cases requiring operation for fibroid after the menopause were very infrequent and hemorrhage at that time was due to malignant disease or the fibroid becoming polypoid. He had never seen a case in which malignant disease had developed in the lesions left by a subtotal hysterectomy.

Dr. DONALD, in reply, referred to Dr. Giles's investigations, which showed that sexual feelings were less influenced by removal of the ovaries and uterus than by removal of the ovaries alone. As regarded anesthetic, he preferred the open ether method.

Thursday, July 30—Second Day.

Management of Pregnancy and Labor in Contracted Pelvis.—Dr. HENRY JELLETT, Master, Rotunda Hospital, Dublin, opened this discussion. He said that, from a clinical standpoint, contracted pelvis might be divided into two main classes, symmetrical contractions and asymmetrical contractions. He would consider the former only, and of this there were two main types, viz., flattened pelvis and generally contracted pelvis. He divided the contractions into four degrees based, to a large extent, on the clinical course in each: (1) Pelvis with a conjugate of over 3¼ inches; in these the child might be delivered spontaneously if of normal size, if the uterine contractions were normal, and if the presentation were normal. (2) Conjugate from 2¾ inches to 3¼ inches; in these vaginal delivery was only possible if the child was below the normal size, as in premature labor, or the pelvis was enlarged as by symphyseotomy. (3) Conjugate 2¼ to 2¾ inches. In these delivery through the pelvis of a viable child is impossible. (4) Conjugate below 2¼ inches. In these delivery of a child through the pelvis is impossible, even after

embryotomy. He would consider the treatment only of cases of the second degree, as in the others, the question might be considered settled. Four courses were open: (1) Induction of premature labor; (2) symphyseotomy; (3) Cesarean section; (4) Craniotomy. With reference to induction it might be said in its favor that for the general practitioner it was easier to perform than any of the other operations, against it were the facts that infection was easy, the methods were uncertain and the child was often weakly and incapable of surviving. Cesarean section was easy, and when done early in labor almost free from risk; it can be performed in subsequent labor. Its disadvantages were that if we were to get full advantage from it it must be done early and patient may not be allowed to try the effect of labor pains and of moulding, so that it will have to be done in every subsequent pregnancy. Pubiotomy had several advantages: it would be postponed until the last moment, so that every opportunity could be given the patient to complete the labor herself, and, what was most important, in his experience, it left a permanent enlargement of the pelvis. Against it could be urged that lacerations of the urethra and bladder might follow; other complications were phlegmasia and necrosis of the bone in two of their nineteen cases the piece of bone between the line of section and the symphysis necrosed, but good union resulted later and neither in these nor in any other of their cases did any difficulty of locomotion result. The normal minimum conjugate for pubiotomy was 7 c.m. in proof of the fact that permanent enlargement of the pelvis followed the operation he mentioned that, in these nineteen cases there had been twenty-nine labors prior to the performance of pubiotomy with twenty-two dead children, while, subsequently, these women had had fifteen labors with only three still births. In conclusion he laid down the following rules for the management of labor in contraction of the second degree: (1) Pubiotomy should be the operation of choice. (2) Pubiotomy was specially indicated in young multiparæ, because of its effect on subsequent labors. (3) Cesarean section was most suitable for elderly primiparæ, because of the danger of tears in doing symphyseotomy on these cases, and the fact that subsequent labors did not enter into consideration. (4) Premature labor was only advisable under special circumstances. (5) Craniotomy should not be done on the living child.

Professor Frank of Cologne said that one hundred years ago people tried to prohibit by law the operation of symphyseotomy as if it were an attempt to murder. To-day it might be called the most successful operation in the whole of midwifery, and it ought to be learned by every accoucheur. The author's subcutaneous symphyseotomy had no danger. In performing it, the outside wound must not be larger than the breadth of the narrow knife, which was the only instrument employed. When the knife left the wound the operation must be entirely finished. The operation was finished when a jerk was felt and the pelvis gaped for several centimeters. The opening in the skin was sutured immediately with catgut. Frank said he had performed this operation in his clinic 155 times. Among the cases were forty primiparæ. None died from operation. A contraindication was narrowing in the fourth degree. Unless the os was fully dilated, one should not operate. The following were the author's conclusions: (1) In cases with large disproportion the classical Cesarean section should be performed if one could guarantee asepsis. (2) If the asepsis was doubtful, delivery by the suprasymphyseal route was advocated. (3) In the middle degrees of narrowing subcutaneous symphyseotomy was to be preferred in multiparæ. In primiparæ, with narrow, soft parts, suprasymphyseal delivery was to be preferred if there was suspicion of infection. In clean cases in primiparæ classical Cesarean section was advised. (4) In primiparæ symphyseotomy was to be considered if there was only slight obstruction to delivery.

Dr. Shannon of Glasgow gave the statistics of the Glasgow maternity for the years 1909-13 inclusive. He estimated the pregnancy of contracted pelvis in Glasgow as 30 per cent., and thought that it was more prevalent than in any other city in the world. There were 1,291 full term labors, and among these 355 cases of contracted pelvis; the presentations in these latter were: vertex, 94 per cent.; breech, 2.5 per cent.; transverse, 2.5 per cent.; face and brow, 1.6 per cent. The average weight of the child was 7 pounds. For diagnosis of obstruction they did not trust to measurements of the pelvis alone, but paid much attention to the size of the head; in borderland cases the patients were anesthetized and placed in the lithotomy position; the head was then pushed down into the pelvis, and its fit estimated by placing two fingers of the other hand in the vagina and the thumb over the pelvis. They recognized three groups of cases: (1) When marked overlapping occurs these require Cesarean section. (2) Minor degrees of overlapping, which could be dealt with by forceps or symphyseotomy. (3) No overlapping; these would terminate naturally. The labor was closely watched, and, if fetal pulse rate was accelerated or maternal temperature rose the forceps was applied. Forceps might be applied too early by the practitioners before proper time for moulding had been allowed; and the amount of force used was often unjustifiable. They never employed symphyseotomy until the natural forces had been allowed to have a chance and two or three moderate tractions with forceps had been made. Pubiotomy was preferred to symphyseotomy. The operation was contraindicated when much manipulation had been done and many attempts at forceps delivery had been made, and they never did it in primiparæ. In case of infection when the woman had been long in labor they did craniotomy.

Dr. F. Hastings Tweedy of Dublin thought that internal measurements were of more use than the "Müller" method, and that we might usually act on the supposition that the child would be of normal size. He considered that the only reliable method of measuring the conjugate was by Skutch's pelvimeter. He would advocate extraperitoneal Cesarean section in preference to craniotomy for infected cases.

Professor Murdoch Cameron of Glasgow advocated examination of the pelvis by introducing the whole hand and examining whilst the head was pressed down from above by an assistant. He showed a pair of antero-posterior forceps which he had found useful.

Professor Kynoch of Dundee had found Walcher's position useful. The first labor should be treated as a test. Induction of premature labor had been far too much criticised and he was of opinion that, if based on careful estimation of the relation of the head to the pelvis it was a very good method. Herff of Basle had elaborated a good method of estimating the relation of head to pelvis; he measured from the spinous process of the last lumbar vertebra to the front of the fetal head above the pubes and compared that with the measurement from the same process to the front of the pubes (external conjugate).

Sir John Byers of Belfast agreed with those who said that cases which had been examined by outside practitioners and midwifes were unfit for Cesarean section. He advocated the greater extension of lying-in-hospitals.

Dr. Oliphant Nicholson of Edinburgh advocated induction. He did it by passing a finger through the os and separating the membranes, or, as an alternative, by packing gauze into the lower uterine segment.

Dr. Jellett, in closing the discussion, said that the knowledge that we have pubiotomy to fall back upon enabled us to allow women to go on in labor until signs of danger arose, and he again emphasized the effect of pubiotomy in leading to a permanent enlargement of the pelvis.

Friday, July 31—Third Day.

Acidosis and the Nitrogen Partition in Pregnancy.—Dr. Leith Murray of Manchester read this paper. He said that Whitridge Williams had modified his original views as to the ammonia coefficient. His own investigations covered eighty cases, normal and abnormal. He employed three tests—Mathison's, Groat's, and Hart's.

Mathison's Method of Ammonia Estimation.—Shake for two minutes 25 c.c. of urine with 15 grammes (circe) of *neutral* potassium oxalate and 50 c.c. distilled water. Neutralize with N 10 soda, using phenolphthalein as an indicator. Add 5 c.c. neutralized commercial formalin. Titrate again with N 10 soda till neutral. Each c.c. = 0.0014.

Groat's Method of Total Nitrogen Estimation.—Add to 2 c.c. urine 6 c.c. concentrated sulphuric acid and a few crystals of potassium sulphate in a Kjeldahl flask. Boil in a fume-cupboard till clear; cool, wash thoroughly into a large flask, and estimate the total nitrogen as ammonium sulphate by the above method.

Hart's Colorimetric Acidosis Index.—Two solutions are necessary: (*a*) Ethylaceto-acetate, 1 c.c.; alcohol,

25 c.c.; distilled water, 1,000 c.c. (*b*) Ferric chloride, 100 grammes; distilled water, 100 c.c. Take two test tubes of equal (½-inch) caliber; in one put 10 c.c. of A., and in the other 10 c.c. of urine. Add to each 1 c.c of B. Dilute the tube containing urine till the two match. The acidosis index per liter equals one-tenth of the volume (cubic centimeters) in the tube of urine. To obtain the index proper (which represents total acidosis estimated in terms of grammes of B—oxybutyric acid), multiply the above by the number of liters passed in twenty-four hours. Quantities of acetone bodies insufficient to give a positive perchloride test, but giving a sodium nitroprusside reaction represent an acidosis index per liter of 0.5.

In fifteen non-pregnant cases the ammonia coefficient was not above 5.5 per cent. in any case; the normal coefficient of non-pregnant cases was 3-5 per cent.; in normal pregnancy this percentage could be increased without pointing to acidosis. Ammonia was formed only by living liver cells and in normal pregnancy there was considerable strain on the liver; in hyperemesis there was degeneration of liver cells. In acidosis the symptoms were not due to acid bodies present, but to the diminution of the fixed bases in the tissues, these having been used to neutralize the acids. The best clinical test of acidosis was to note the tolerance of alkali as seen in its effect on the urine. Five grammes of sodium bicarbonate were given every six hours; in normal individuals this made the urine alkaline. In testing for the ammonia coefficient it was better not to use a mixed specimen of twenty-four hours urine, but to perform the test on specimens taken every three or four hours, as great variations may occur throughout the day. The coefficient became higher in pregnancy, and he had seen it 13 per cent. even in the absence of symptoms. In toxemic cases he had seen it 25 per cent. This was relieved by emptying the uterus, after other methods of treatment had failed. In five cases of eclampsia it varied from 13 to 18 per cent. He agreed with Whitridge Williams that only by comparing clinical symptoms with laboratory results could we arrive at a just estimation of the importance of the ammonia coefficient.

Dr. Russell of Glasgow was convinced that the interior supplied by Whitridge Williams was a valuable one as an indication of the necessity of active treatment.

Further Observations on the Treatment of Eclampsia by Veratrine.—Dr. Haultain of Edinburgh, president of the Section, read this paper. The dose he gave was 1 c.c. by hypodermic injection. This reduced blood pressure in a marked degree and increased the excretion of urine. He found that if the pulse was reduced below 58 by the drug, vomiting occurred. The outstanding feature of eclampsia, in all cases, was high blood pressure, both before and during the fits, and he thought that this was an element in the causation of fits. He had made experiments on cats and found that, in small doses, there was a fall of blood pressure, but no effect occurred when the vagi had been cut, showing that the effect was produced through action on the vasomotor centers; but it had also a probable action on the toxemia, as fits did not occur after its use, even when the blood pressure had risen again. He had tried it in seventeen cases with one death.

SECTION OF MEDICINE.

Wednesday, July 29—First Day.

Dr. J. F. Smith of London in the Chair.

Headache.—Dr. Hurry Campbell opened the discussion on this topic. It was necessary, he said, to distinguish carefully between true headache and cephalic dysthesias, such as constriction of the head, heaviness or lightness, confusion, vertigo, etc. The assumed center for head pain was in the lower part of the post-cerebral convolution and the connection of this region with the center of spinal sense explained headaches due to eyestrain, to loud noise, etc. In speaking of headache due to gastric and intestinal disturbances he deprecated the tendency to avoid meat, which he regarded as especially digestible.

Dr. C. O. Hawthorne discussed the relation of headache to high blood pressure, indigestion, and alimentary toxemia. In plethoric conditions he had found much benefit from the application of leeches to the temples.

Dr. L. H. Pegler called attention to headache occurring as a nasal reflex or due to malaeration of the blood or lymph stains due to nasal obstruction. There were no definite characteristics of a nasal headache as distinguished from that due to other conditions. But if examination showed obstruction or inflammation within the nasal passages, the removal of these pathological states would often cause the disappearance of the head pain.

Dr. F. C. Eve referred to the headache caused by increased tension of the cerebrospinal fluid and also to toxemic headaches among which was the pain so often noted after tuberculin injections.

Dr. F. J. Smith said intractable headache might be due to undiagnosed syphilitic infection and could in such cases be cured by mixed treatment.

Dr. Campbell said the diagnosis of a specific headache might be extremely difficult since in many cases of active syphilis the Wassermann reaction might be negative and the cerebrospinal fluid might also give no signs of the disease.

Splenectomy in the Treatment of Anemia.—Dr. J. S. McKendrick read a paper with this title, in which he advocated the removal of the spleen as a therapeutic measure in certain forms of anemia. This organ, he said, whatever its function might be, had been shown not to be essential to life.

Dr. L. P. Phillips reported a case of splenomedullary leucemia in which apparent cure had been obtained by the administration of benzol. He urged care, however, in the use of this drug, as it was a very powerful poison.

Sir William Osler said that rapid enlargement of the liver occurring in the course of splenic leucemia with splenomegaly was usually an indication for the operation of splenectomy.

Dr. J. R. Charles reported three cases of splenomedullary leucemia, in two of which splenectomy was performed, the third being treated, with but temporary success, by benzol.

Patent Ductus Arteriosus.—Dr. T. Wardrop Griffith reported two cases of this anomaly, illustrating his paper with lantern slides.

Thursday, July 30—Second Day.

Artificial Pneumothorax in Pulmonary Tuberculosis.—Dr. Rist of Paris opened this discussion. He said that this form of treatment had been under observation for quite a long time, but that only in 1906 did any one make a decisive step to prove its usefulness. He discussed many of the interesting points in connection with the disease and perhaps he laid most stress on the value of *x*-ray photographs as a means of diagnosis and the extent of the lesions involved in the lung. He discussed the types of cases which were most suitable for this form of treatment and the means by which fatal results must be prevented. He believed that by more extensive use many cases which at first sight seemed hopeless might have life prolonged by this treatment, and those who were destined to become invalids for the rest of their lives could be made fit and able to return to work. Dr. Rist discussed the physiology of respiration and showed how the potential cavity between the two layers of the pleura could have its negative pressure altered. This pressure, equal to about 6 mm. of mercury, was increased by inspiration and decreased by expiration. If the latter was violent then the pressure became a positive pressure. The lung did not fully collapse, owing to the amount of elastic tissue it contained. Now if nitrogen were placed in the pleural cavity the lung slowly collapsed and would eventually lie flat against the mediastinal contents if sufficient gas were introduced, and gradually the pressure passed from negative to positive. If the lung had undergone pneumonic consolidation or was filled with masses of caseating tubercle, as he related occurred in some of the patients under his care, the intrapleural pressure would give a positive reading before the organ fully collapses. Several days after the pressure was negative, due to the intrathoracic structures yielding to the resistance of the lung, and not due to the absorption of nitrogen. The lung finally became immobile. Dr. Rist showed that as the lung collapsed the other structures there collapsed also and forced out any contained secretions and prevented their accumulation. Cavities when present were obliterated by the approximation of their walls and the contents were expelled. All hemorrhage was arrested. Some believed that artificial pneumothorax should be a last resort, but only after four months of sanatorium treatment had failed. Progressive cases should be treated by this means.

Acute lesions responded better and earlier than old fibrotic lung cases, as then there was less chance of adherent pleuræ. Every suspected pulmonary tuberculosis case should be subjected to *x*-rays. These photographs should be taken at varying intervals and the difference in condition noted. When there were no signs of improvement then the experimental method must be tried. Sudden hemoptysis was a sign that the disease was progressing, and from a point of view of treatment the method of lung displacement should be begun. The position of the lesion was discussed. It was better when it was in one lung only, though there was no reason why a perfect cure should not be got when both lungs were affected, provided there was enough sound tissue left to carry on the function of respiration. If artificial pneumothorax was attempted on one side, and the other side was also affected and only a little healthy tissue left for respiration, the patient died from asphyxia. The method of treatment consisted in keeping the patient in bed for some time previous, except in cases where displacement was urgently required to check a hemorrhage. One must always note cough, expectoration, temperature, etc. Some men gave morphine, but the speaker said he gave it only in certain cases because it masked many of the signs which one wanted to find out. He did not deal with the instruments used for the operation nor with statistics of cases he had dealt with. The lecturer went on to deal with the amount of gas injected. When the needle reached the pleural cavity the manometer indicated the pressure therein. A long inspiration gave a still further negative pressure, while coughing gave a positive indication in the tube. It was not necessary to push the needle right into the lung to get it to collapse. Dr. Rist injected a fairly large quantity of nitrogen at the first attempt, and did not do as some did, injecting a small quantity first and then increasing its amount by subsequent operations. The average pleural cavity contained about 3,500 c.c. of gas, but one could be sure that the lung was fully collapsed only by means of *x*-rays. If the lung was not extensively diseased a pressure varying from + 1 upwards indicated complete collapse. If the organisms consolidated it might be only two-thirds displaced when this pressure was reached. Several days later the pressure was again negative and more gas could be run in. The presence of adhesions were often a source of difficulty to the operator, and the difficulties which arose varied with the character and extent of these adhesions. The finding of the pleural cavity was a very difficult matter and one may know he has reached it when the manometer reading began to oscillate. Pleural adhesion was common, occurring in at least 50 per cent. of the cases. Numerous small and transient effusions were found commonly. The pleuroscope showed these up quite well. The amount of fluid might be half an ounce. The disappearance of the effusion was shown by this instrument also. The presence of fluid might not affect patients, but it did so in some. If after pneumothorax had been performed a fever occurred then usually an effusion had occurred, and Dr. Rist said that tapping did not help much unless the pleural cavity had got half full of fluid. Then nitrogen was pumped in and the manometer reading kept constant. Experiments had been tried on guinea pigs by inoculation with tubercle bacilli. Very small sacs were found to contain pure esinophile and mast cells, but this fluid did not become purulent.

Drs. Woodcock and Clark of Leeds also took up the question of artificial pneumothorax. They discussed its advantages and disadvantages when the different degrees of pathological thickening of the pleura occurred. Dr. Clark described the method of operation. A point was usually selected in the fifth intercostal space in the midaxillary line. The part selected was made thoroughly aseptic and the operation proceeded with. He dealt with the rate at which the gas should be injected and said that with caution gas embolism never occurred. Two cases under his care were reported and both had turned out successfully.

Friday, July 31—Third Day.

Tuberculosis in Infancy and Childhood.—This was the subject of a joint discussion of this Section and that of Diseases of Children.

Dr. D. B. Lees said children were specially susceptible to tuberculosis, the infection of which was often marked by symptoms recalling those of rheumatic fever. During the past few years the *x*-ray had given good service in the diagnosis and in exposing the lesions of this disease. The question was asked whether tuberculosis in children could be diagnosed by physical examination alone, without the *x*-rays or bacteriology. The speaker thought the ordinary measures of inspection, palpation, percussion, and auscultation were sufficient if carefully and methodically used. All muscles must be relaxed and the patient must be recumbent, or, for examination of the back, sitting and stooping slightly. Percussion often showed evidence when auscultation was negative, and *vice versa*. He said the distribution in the lungs was always the same and symmetrical in as far as the lobe division permitted, and quite different from the areas of atelectasis, infarct, etc. He showed a diagram with the lesion areas marked. There were dull areas at the apices of the upper and lower lobes; these were the chief ones. Dullness, due to enlarged glands, in asthma, etc., lay between these areas. Another, working independent of these percussion results, could confirm these conclusions by the *x*-rays. Examination should be made monthly with a permanent record taken in finger-breadth measurement. Dull areas should be marked in a simple diagram. All this refers to adults and adolescents as well. In children there were special features distinguishing the clinical picture from that in adults. Tuberculosis in children was much more liable to spread by the peribronchial lymphatics and was much commoner on the right side, probably because of the relations of the glands. The glands when infected swelled and pressed on the vagus causing asthmatic or croupy symptoms. A gland might burst into a bronchus causing pneumonia, miliary turerculosis, or emphyema. Peribronchial tuberculosis fibrosis, etc., had characteristic skiagrams. No sound conclusion could be made on a screen examination without a photograph. Even with a photograph the greatest technical skill was required and the highest knowledge was called for in interpreting it. The rays might project an area of dullness on to a different area. Careful percussion would detect these fine incipient changes as well as very large areas and give their true situation while there were yet no morbid sounds. Children were very liable to mixed infections. An apparently simple bronchopneumonia was often found followed by tuberculosis. When an apparently simple bronchopneumonia was found one should examine these apices. Fatal tuberculosis in children began oftenest in the lungs—not the intestines. Common lung troubles that seemed to become tuberculous were probably lesions in an already infected child or tuberculous infection was mixed with the prominent one. Careful physical examination was within the power of every general practitioner without a laboratory, and he could regulate his treatment by the knowledge so acquired. When every man realized this we might hope for the extinction of pulmonary tuberculosis.

Dr. Clive Rivière said that chronic pulmonary tuberculosis in children was nothing more than a curiosity. The glands bore the brunt of the first infection and it was therefore first a tuberculosis of glands from whence it might spread elsewhere. It began in the glands and first became a hilus tuberculosis. This form was much commoner than apical phthisis in children. From it phthisis might develop. Such cases were found rather in the school than in the hospital—little seen and seldom recognized. The course of the affection was uneventful and its treatment local. Interscapular dullness of the Leblanc was one of the oldest signs of enlarged chest glands. With gentle percussion and röntgenoscopy we could get early physical signs. Interscapular dullness as an early sign was found on the right side only. Pressure on the right pulmonary artery is the cause of this probably. The *x*-rays show signs on the left side also. This sign alone was present in two-thirds of a group of seven children showing *x*-ray signs. Normally there was an area of impaired note from the first to the fifth dorsal vertebrae. An increase in the dullness and size of the area constituted the sign. The outer limit was curved and varied with respiration. The signs differed from those of apical involvement. In gland impairment the apex was less affected than the interscapular area and dullness might be found only on the back. In apical tuberculosis the apical dullness was the better marked and more constant. On auscultation one gets sounds, but when the glands chiefly are involved râles are rare.

In phthisis the diagnosis was much the same as in adults only one cannot as a rule get sputum evidence. Blowing sounds, especially on the right, must be carefully interpreted. Very light percussion must be used. This gives the earliest and most reliable results. All signs should be taken together and one should not rely too much on auscultation. Dull areas once present might persist for the remainder of life and were no evidence of active disease. If active they enlarged and this could be charted.

Dr. BRUCE of London said that fluid and fibrous tissue offered more resistance to the *x*-rays than normal lung. The screen was useful for studying the movements of the lung, diaphragm, etc. Photographic methods were necessary for fine details. Short exposures were now possible. If the diaphragm had moved during exposure the plate was not reliable. He went on to describe the screen-appearance of an affected chest and to discuss the probable causes of these appearances. Typical appearances might, however, go on to other pictures—shadows might enlarge and overlap and thus form large masses. Fluid formed large opacities obliterating all else, but had a sharp outline. Different conditions accompanied by fluid could be distinguished. Hydatid cyst had a sharp outline.

Dr. EVE of Hull said that glandular and pulmonary forms of tuberculosis were often confused and unless they were distinguished one could not go far. He mentioned the physical signs as he had found them in both classes. He knew of only one death in a child with suffocative attacks. At autopsy a gland was found to have ulcerated into the trachea. He asked Dr. Bruce if *x*-rays could distinguish between the two cases.

Dr. MACHEIL of Edinburgh asked Dr. Revière whether he meant that dull areas were found in all cases at the apices. He said there was no proof in this country either from autopsy or tuberculin tests that a tuberculous infection, latent or active, was universal. He expressed a doubt of the dullness always meaning a tuberculous lesion. Clinicians were going back to adopt infection of the apices from the neck glands though pathologists now had given up the theory of infection from the glands direct. He wished to distinguish between latent and active apical lesions. The tuberculin test was a far more delicate test than the percussing finger. Apical tuberculosis, whether latent or active, was rare in children.

Dr. LAWSON of Banchory asked whether the ordinary clinical method or *x*-rays were the more reliable. He said that one ought to combine these. The only rational method was to combine all our means of diagnosis. The *x*-rays would detect dullness. He had known apparently typical tuberculosis of the glands turn out to be malignant disease. He thought that endothelioma, etc., in children was insufficiently considered. He attached the greatest importance to limitation of diaphragm movement in early cases. He also asked if transillumination phenomena were studied. It was important to be able to say whether the fluid in a child's pleura was clear or purulent. Ten years ago, in experiments with rubber bags, he had found almost no difference in the shadows, and he wished to know if this had been investigated.

Dr. LANGMEAD of London said he had not Dr. Lees' optimistic opinions. Tuberculosis was very common in children. Eighty per cent. of the tuberculin tests in Vienna in school children were positive, yet physical signs failed. His opinion was that tuberculosis often failed to be diagnosed when present even with most careful examination. *X*-rays did not tell whether a lesion was active. Repeated physical examination was required. He insisted on taking everything into consideration—not percussion or röntgenoscopy only.

Dr. PREST of Ayrshire said it was necessary to determine whether the disease was active or not. He always inquired carefully into the history, if there was sweating, if the patient quickly tired, or was losing weight, etc., and he treated any symptoms that arose. He relied more on symptoms than on signs which many were unable to appreciate. In addition to percussion, the sound of the whispered voice was extremely useful in detecting consolidation.

Dr. BARTY KING of London said that in 35 per cent. of the cases sent to his clinic as definite pulmonary tuberculosis, after most careful scientific examination, he could find no tubercle bacilli, hence deductions from examination must differ widely. In one case *x*-rayed by Dr. Jordon and reported undoubted peribronchial tuberculosis, but with kidney disease, sections after the autopsy showed thickening of the bronchial walls and peribronchial tissue but no tuberculosis. What they wanted from the *x*-ray department was a report of what they saw and also what their interpretation was.

Dr. F. J. SMITH of London, President of the Section, said they were face to face with not a quarrel, but two points of view. One relied on physical signs; the other wished to know whether the child was ill or not and what the prognosis was. Very little had been said as to symptoms and nothing as to the organism. Statisticians annoyed him by ignoring symptoms. He spoke of the advice given in sanatoria to departing patients. Each had a fetich which they studied—not the patient. He said that more attention should be paid to the patient's symptoms than to his temperature or the skiagram.

Dr. LEES said the dull areas were not universal in children's chests. These dull areas were frequently found in children and the results agreed closely with tuberculin results. The discovery of dull areas did not prove active tuberculosis. The areas diminished in size but did not disappear on recovery. The case should be kept under observation in order to determine whether or not it was active. In children the difference between apical and hilus tuberculosis was marked, but they were only different types of the same disease. Until physicians improved their skill in percussion they would not make much progress. He remarked on a patient who was gaining weight until tuberculin treatment was started, when emaciation set in. The treatment was regulated by ausculation only.

Dr. RIVIÈRE said one was apt not to differentiate between tuberculous infection and tuberculous disease. Symptoms had to be carefully inquired into also in diagnosis.

Dr. BRUCE was of the opinion that the caseating gland in the fatal case could have been easily made out. He did not believe that fluids could be differentiated by the *x*-ray unless one could do so from the condition of the viscera. He said catarrhal but not fibroid changes could be diagnosed.

SECTION OF SURGERY.

Wednesday, July 29—First Day.

The Etiology and Treatment of Carcinoma of the Tongue.—Mr. W. G. SPENCER of London opened the discussion of this subject. He said that it had been the hope of those who had paid special attention to cancer like the late Sir Henry Butlin that by recognizing and removing the conditions which were destined to become cancerous, or what practically came to the same thing, cancer in its earliest stages, a safe cure without deformity might be insured. This would offer an escape from the vicious circle of severe and deforming operations, so often followed by recurrence because done too late. Owing, however, to the introduction of fresh methods of treating inflammatory conditions, such as the administration of salvarsan, exposure to radium *x*-rays, further hindrances to the incision of cancer in the earliest stages had arisen. It was a fact of first importance that an inflammatory condition existed on the tongue for a time before carcinoma actually commenced. Such lesions were well known under the names of chronic superficial glossitis, leukoplakia, papilloma or wart, chronic ulcers or fissures, and irritable scars. There were causes of delay which are due to patients; but there are also many of these in which the disease had for some time been under the observation of a medical practitioner. In the syphilitic lesion the Wassermann reaction was now an aid to diagnosis and salvarsan has proved a valuable adjunct to mercury in clearing away chronic affection, which otherwise would have gone on to cancer. But salvarsan had no influence on old standing lesions and certainly none when a new growth was about to begin unless there was an absolute improvement, going on to healing, within a fortnight of the administration of salvarsan recourse should be had to surgery. Smoker's patches should disappear on the cessation of smoking, if not, cancer might supervene, it might be years afterwards. A dental ulcer should heal at once on removal of the offending tooth. In one case five weeks after the bite the ulcer after excision, was found to exhibit commencing epithelioma. Two other cases in which the date of the bite was definitely fixed at ten weeks before that of the excision of the ulcer, epithelioma had already become widely diffused, and both died from secondary disease which appeared beyond the limits of

the extensive excisions. Oral sepsis was a grave complication increased in rate of growth of the cancer. But whether the oral sepsis *per se* was a cause of cancer in the mouth was a different proposition altogether and one which appears to be non-proven. The lesions which went on to cancer were marked by a proliferation in the epithelium and at first there was no change in the subepithelial tissue. There followed a small cell infiltration of this subepithelial tissue and next a down growth of epithelium. When this last had occurred it must be assumed that among the small round cells there were cells derived from the epithelium which would later prove epitheliomatous. There followed in the lymphatic sinuses of the lymph glands which received lymphatics from the affected portion of the tongue a collection of small round cells. Here it was also necessary to assume that some of these small cells were descendants of epithelium, which would develop epitheliomatous characteristics. But clinical observation tended to support the further assumption that at this stage of the disease, no epitheliomatous cells had been arrested in their course to the lymph gland. The exceptions were cases when the malignant disease diffused widely from the first but these were hopeless. A case quoted had a primary growth on the tongue which only measured 1.5 cm. in diameter, yet malignant glands in the posterior triangle of the same side had already become inoperable, having partially broken down and a foul sinus having formed.

The term precancerous is too indefinite a term and it was best once for all to include the zone of small cell infiltration as part of the cancer. This was comprised by the observations of E. Bashford and A G Murry on the transmission of squamous cell cancer in the mouse. Superficial lesions in which the small cell infiltration of the subepithelial tissue was absent showed no tendency to develop epithelioma in the specimens exhibited. Removal of the chronic lesions by excision were free from risk—when the patch was small and single there was no impairment in the movements of the tongue—generally, one should avoid removing more epithelium than was necessary in order to avoid loss of articulation and difficulty in swallowing. The patient's enjoyment of life and his occupation demanded consideration. The best way of recognizing that epithelioma had already invaded the subepithelial tissue, was in a microscopic section made immediately from the piece excised, the surgeon waiting and the patient being kept under the anesthetic. This overcame the very real objection that the patient might refuse to undergo a second operation until too late. When the cancer was found to have already invaded the subepithelial connective tissue, the portion of tongue incised should be enough to include all the small cell infiltration. The surgeon should then proceed to a dissection of the anterior triangle of the corresponding side. This dissection should be restricted to the lymphatic glands above the omohyoid muscle along with the platysma and deep fascia. But in the stage of the disease above mentioned the mylohyoid muscle and hypoglossal nerve should be spared in order that the patient might recover food articulation. Also there should be no communication opened up with his mouth and then the wound in the neck might be expected to heal by first intention. The additional dissection of the opposite anterior triangle was indicated whenever the disease approached to or lies across the middle line. Cases were quoted and the specimens of the diseased shoulder from the patients who had remained not only without recurrence but without any impairment of speech and swallowing. But when the epithelioma had already invaided the muscular substance of the tongue, and further when the corresponding lymphatic glands also showed an epitheliomatous invasion then it was necessary to remove the disease *en masse* or *en bloc*. Some favorable cases on freedom from recurrence might be insured without importantly impairing the patient's power of articulation. But the more extensive operation involved an immediate risk to life, impaired articulation and deglutition and the patient was liable to suffer from recurrence, even many years after. Perhaps the most distressing feature in the advanced stage of the disease was the suffering of the patient in whom there is recurrence. These larger operations involved variations in procedures about which there might be wide differences of opinion. Among such questions were: (1) How far might the more typical operation be modified to meet emergencies in individual cases? (2) Should the sternomastoid muscle and the spinal accessory nerve be moved along with the glands lying underneath? (3) Should the internal jugular vein be excised? (4) The ligature of the common carotid and of the internal carotid seems to be always contraindicated. (5) The extension of the dissection to the root of the neck is a dangerous procedure but it might be proper to run the risk. Division and excision of a portion of the mandible increased the danger; the excision of one-half of the mandible appeared safer. (6) The horizontal division of the cheek caused a deformity and did not appear to have any redeeming advantages. (7) A preliminary laryngotomy was of great value in important cases. Owing to the difficulty of introducing the tube in such cases intratracheal insufflation involved more risk. Intravenous ether anesthesia in skilful hands had advantages when a preliminary laryngotomy was unnecessary. Preliminary injection of morphine appeared objectionable as impairing respiratory movement after the operation. (8) It was advantageous to diminish raw surfaces by applying sutures between the remaining portions of the tongue and the buccal mucous membrane, also by inserting deep sutures to shut off a communication between the mouth and neck. (9) Difficulties with food after the operation were best overcome by a tube passed through the nose. A catheter kept in the esophagus was objectionable; preliminary gastrostomy was preferable.

The results of operations might be summarized as follows: (a) The incision of chronic lesions of the tongue was wholly successful before the epitheliomatous invasion of the submucous tissue had occurred. The patient would remain free provided that the original cause did not produce fresh patches on the tongue. (b) Incision of an epithelioma, including the zone of small cell infiltration together with the corresponding lymphatic glands was successful when the epithelioma had not already extended into the muscular substance of the tongue, and when the lymphatic glands had not been invaded by actual epithelioma. The operation did not invoke risk to life. No important deformities persisted; the patient need not fear late recurrences. (c) When epithelioma had infiltrated the muscular substance of the tongue, and when there is already an epitheliomatous infiltration of lymphatic glands, then varying with the extent of the operation and the condition of the patient previous to the operation, there was a risk of death after the operation, and deformity followed. In the less malignant cases there was a prolongation of life, but the three years limit passed, there was still no certainty that late recurrence might not supervene. A few cases, of which instances were quoted, were benefited by secondary operation and they might even be thus freed from the disease.

In the palliative treatment of inoperable cancer, the greatest relief was afforded by reducing the septic decomposition on the surface by continuous use of non-irritating antiseptics, and the administration of opium, aspirin, phenacetin, etc. There seemed important drawbacks to other proposals, the division of the lingual nerve was useless; drugs tended to excite the development of the lymphatic glands, also radium inserted caused great pain, and might be followed by rapid infiltration as in the cases cited; diathermy affords temporary relief by killing the organism on the surface, but its use was necessarily occasional, whereas antiseptics can be used continuously; adrenalin injected to reduce congestion, favored necrosis and so made things worse.

The Lymphatics of the Tongue.—Professor J. KAY JAMIESON and Dr. J. F. DOBSON of Leeds read this paper. They said that the primary glands were the submental, submaxillary, and some members of the deep cervical chain, i.e., the jugulodigastric gland, the members of the upper deep cervical group on the great vessels at and below the level of this gland, and some members of the lower deep cervical group notably the jugulo-omohyoid gland, the anterior outpost of this group lying on the central tendon or anterior belly of the omohyoid. There were three sets of vessels, marginal, central, and posterior which ran to the primary glands without interruption. The marginal vessels ran through the mylohyoid close to the jawbone and along with the lingual blood vessels. The central vessels draining the greater part of the upper surface descended in the middle line between the genioglossi and then turned out with the lingual blood vessels. The posterior vessels from the region of the circumvallate papillæ and back of the tongue ran towards the hyoid and then turn outwards to pierce the pharyngeal wall below the tonsil to reach the deep cervical glands. Vessels from the tip and region of the frenum might cross the middle line and reach glands of the opposite

side. Some central vessels from the right side of the dossum turned outwards to the opposite side glands. Posterior vessels near the midline often bifurcated and reached the glands of both sides. Only the lateral marginal vessels were confined to one side in distribution to the glands. The vessels ended in the following way. The deep cervical glands (jugulodiastric, jugulomohyoid, and the glands between them) received vessels from all parts of the tongue; the submaxillary from the whole area in front of the circumvallate papillæ and the submental only from the tip and region of the frenum. It was to be noted that the most posterior marginal vessels, and the posterior vessels might wind round the outer side of the external carotid artery on their way to the deep cervical glands. In cases of cancer of the tongue adequate removal of the glands diseased or likely to be diseased could only be effected by an operation performed on the lines of Crile's block dissection. A bilateral gland operation was indicated in a growth of the tip, frenum, or back of the tongue, and in cases of growth commencing on the lateral border but extending towards the middle line. The unilateral operation should be reserved for cases of early growth of the lateral border of the tongue.

Dr. C. P. CHILDE of Southsea advocated the dual operation, and whenever the patient's general condition was sufficiently good he preferred to do the operation at one sitting in the following order: removal of glands and lymphatic tissue, ligature of lingual artery or arteries, excision of the tongue wide of the disease. In cases involving the floor of the mouth, the lymphatic glands on both sides required removal, and this procedure as a rule necessitated a two-stage operation. He laid stress on the urgent necessity of early operation on cancer of any organ, and submitted a leaflet issued by the Town Council of Portsmouth for the education of the public in regards to early signs of cancer.

Mr. E. HEY GROVES of Bristol advised division of the lower jaw because of the free access to the front of the tongue and to the floor of the mouth thereby obtained. The section should be V-shaped so as to insure exact coaptation and easy fixation with a wire suture. In his opinion the best mode of administration of an anesthetic is the intratracheal.

Dr. T. K. DALZIEL of Glasgow laid stress on the frequent presence of an infected gland close to the mastoid process at the base of the skull. He cited cases in which he had successfully removed the tongue, pharynx, and larynx for cancer of the base of the tongue. In the after treatment the mouth was treated as a large granulating area by gauze packing, food being given through a nasal tube, and breathing carried on through a tracheotomy tube.

Mr. MCADAM ECCLES of London drew attention to conditions precedent to the invasion of cancer as illustrated by multiple papillomata of the bladder due to infection from the *colon bacillus*, and skin lesions of the digits induced by exposure to *x*-rays. In each of these examples there was a source of chronic irritation; but only a proportion of the morbid patches became cancerous. With regard to operation his practice was to remove the glands before excising the tongue.

Prof. CAIRD of Edinburgh said it was well to have an opportunity of exchanging experiences and he apologized for dwelling upon his own, although they might present some geographical variations from what had been so ably submitted by Dr. Spencer. His belief was that the diagnosis of lingual carcinoma was easy, and that, moreover, no morbid tissue was more readily recognized under the microscope. All the so-called "precancerous conditions" he had encountered either had been already malignant, or remained simple and yielded to simple treatment under observation. He had not found that syphilis played the rôle so frequently attributed to it as a factor. He now generally employed novocain as a local anesthetic, and with it, it was possible to carry out most complete intrabuccal operations without pain or difficulty. In every case he removed the entire half, or both halves, of the tongue at the first sitting, as by so doing the septic original focus was got rid of, and there could be no further propagation by the lymphatic channels from that source. No gag was required, and Whitehead's or Syme's method was selected according to the requirements of the case. After 10 days, under general, or with local, anesthesia all the lymphatic structures along with the submaxillary and a portion of the parotid glands and such veins as were in too suspicious proximity, were removed in one sheet from the submaxillary region to the sterno-clavicular articulation. The identification of the lymphatic structures was easier at the second sitting from the inflammatory reaction which followed on the primary removal of the tongue. At the second sitting it was well to open into the mouth, thus dealing with any remains of the hyoglossus and lymphatic elements about the mylohyoid muscle. The mortality of such operations was remarkably low, but unfortunately the ultimate prognosis was very uncertain, the most promising cases turning out badly and *vice versa*. Recurrence was frequent, but rarely occurred in the mouth or vicinity of the hyoid bone; it rather favored the lower postauricular area. He only removed the lymphatics on both sides of the neck when very definite indications for this course were present.

Mr. A. LUCAS of Birmingham had found a high proportion of his cases of cancer of the tongue giving a previous history of syphilis; and he also noted that arterial sclerosis was a common concomitant.

Mr. SPENCER briefly replied on the discussion. He held that permeation of lymphatic vessels by cancer cells was certainly not true in the early stage of lingual cancer; and he believed that division of the jaw added to the risks of operation, and was not infrequently followed by necrosis.

The Newer Indications for Removal of the Spleen.—Mr. SIDNEY A. BOYD of London read this paper. He said that for many years splenectomy had been performed for various pathological conditions localized to the spleen, but more recently a number of medicosurgical conditions had been treated by splenectomy with considerable success. A brief account of these conditions was given and the indications for operation were discussed: (1) *Splenic anæmia.*—The term was restricted to those cases which showed an enlarged spleen with oligocythemia, a low color-index, no leucocytosis but usually leucopenia, and a tendency to gastrointestinal hemorrhage and to pigmentation of the skin. "Banti's disease" was the terminal stage of splenic anemia and was characterized by the same symptoms with, in addition, cirrhosis of the liver, ascites, and sometimes jaundice. The treatment of uncomplicated splenic anemia is splenectomy, which should be performed as soon as the diagnosis is made. Apart from operation the disease, although protracted, was progressive and eventually fatal. A successful result was much more likely if the operation was done before the onset of cirrhosis and ascites. Nevertheless, even in this late stage, the operation afforded considerable hope of success. (2) *Chronic acholuric (hemolytic) jaundice.*—This disease differs from splenic anemia in that a hemopoietic reaction was shown by the blood-forming organs, whereas in splenic anemia there was aplasia of these organs. There were two main types, acquired and non-acquired. The latter might be either congenital or familial. In both types there was enlargement of the spleen and anemia, which might be severe, and often there was an increased fragility of the red cells. The acquired cases usually terminated in from six to twelve years in cirrhosis of the liver and ascites, and the non-acquired might end in the same way. Splenectomy had give most encouraging results in both types of the disease. The author referred to a case of his own successfully treated by splenectomy. (3) *Pernicious anæmia.*—The occurrence in some cases of pernicious anemia of increased fragility of the red cells, increased hemolysis, and acholuric jaundice point to the possibility of a common origin with acquired hemolytic jaundice. Histologically, the spleens are very similar. Hence it was not surprising that splenectomy had proved highly beneficial in several cases of pernicious anemia, and the operation was to be recommended, especially in those cases which showed increased hemolysis. The blood picture after a successful splenectomy in these cases differed from that which occurred in the natural remissions of the disease. (4) *Splenic anemia of infants.*—This was a disease occurring in children from six months to two years of age, often with a syphilitic taint, and was characterized by severe anemia, enlargement of the spleen and sometimes of the liver, oligocythemia with presence of normoblasts, and myelocytes, and leucocytosis. Many cases recovered under medical treatment, but the mortality was high. Two cases at least had been treated successfully by splenectomy. The operation should be performed if the child was going down hill. (5) *Gaucher's disease.*—This was a rare affection with an insidious onset, usually before the age of twelve years. There was progressive enlargement of the spleen and liver and pigmentation of the skin of exposed parts.

There was a simple anemia with leucopenia and a tendency to hemorrhage from nose and gums. Brill's sign might be present and be pathognomonic. The pathological changes in the spleen were characteristic. Splenectomy had proved more beneficial than any other form of treatment, but should be performed early. (6) *Cirrhosis of the liver.*—In both Lænnec's cirrhosis and hypertrophic biliary cirrhosis there was reason to believe that the condition of the liver might be unfavorably influenced by the state of the spleen. Splenectomy should be given an extended trial in both conditions. The author referred to a successful case of his own of "splenomegalic cirrhosis," and discussed how splenectomy produced its favorable effect in cases of cirrhosis with ascites. (7) *Acute yellow atrophy.*—There was some evidence to show that splenectomy might prove valuable in these cases. (8) The question of operation in cases of simple splenomegaly was dealt with and the author concluded that it should be performed if the enlargement was progressive or if the general health was deteriorating without any other known cause. The mortality of the operation of splenectomy was discussed, and by performing it in the early stages of the diseases in which it is indicated, he thought it could be reduced to 5 per cent.

Practical Considerations in the Diagnosis and Treatment of Abscess of the Cerebellum with a Record of Cases Subjected to Operation.—Sir WILLIAM MILLIGAN of Manchester read this paper. He said that whereas it was generally taught that cerebral abscesses occurred twice as frequently as cerebellar, his own experience was singular in that he had seen three times as many cerebellar as cerebral abscesses. The largest number of cases were found between the ages of ten and thirty, males being affected twice as frequently as females, and in his experience abscess on the left side was twice as frequent as on the right. In acute cases the usual sequence was the formation of an extradural abscess in the posterior fossa, or thrombosis of the lateral sinus, with secondary infection of the brain. In chronic cases, labyrinthine suppuration was the primary condition. Hence the importance of differentiating between cerebral, cerebellar, and labyrinthine suppuration. No sign was of more value than nystagmus, when properly interpreted. He analyzed this sign in detail, and discussed the caloric tests by hot and cold water. The coordinating functions of the cerebellar hemispheres were considered, and also the disturbance of equilibrium induced by localized lesions, and the significance of Barany's pointing-by test. He considered the ideal route of approach to the usual site of a cerebellar abscess (anterior part of lateral lobe) to be through the posterior wall of the petrous bone in the space between the lateral sinus and the internal auditory meatus; and he preceded the exploration by withdrawing a few drams of cerebrospinal fluid by lumbar puncture in order to lower intracranial pressure, and thus obviate the well-known risk of sudden respiratory failure. To facilitate drainage of the abscess he made a counteropening behind the groove of the lateral sinus. During the last ten years he had operated on 27 cases (17 males, 10 females), of which 20 were cases of cerebellar abscess on the left side and 7 on the right; the results of the operation were 17 cures and 10 deaths.

Three Cases of Abdominal Aneurysm Treated by Operation.—Mr. DE C. WHEELER of Dublin gave a description of the end results of three cases of abdominal aneurysm treated by operation. One case was alive and well nearly four years after operation; a second was seen eleven months afterward and was then apparently well—all signs of the tumor had disappeared. The third case died from rupture of the sac secondary to intestinal obstruction on the fifth day. In each case Colt's apparatus was used. Mr. Wheeler thought there was now no alternative to the coiled wire recommended by Colt, and deprecated the use of electrolysis. It was necessary to be certain by a free flow of blood that the cannula was in the lumen of the sac before introducing the wire, otherwise the latter might penetrate among the laminated clots and not enter the cavity of the sac. The "gall-bladder" position of the patient facilitated the operation. A striking feature in each case was the internal pain in the back from which the patient suffered before operation—due according to the speaker to the tugging and stretching of the peritoneum of the posterior parietal wall. The patients were treated with salvarsan and mercury, and horse serum was injected by Mr. Wheeler before the operation in order to promote coagulation.

Thursday, July 30—Second Day.

The Surgical Treatment of Arthritic Deformities.—Mr. ROBERT JONES of Liverpool opened the discussion of this subject. He said that cases classified as tuberculous were often hereditary, septic, or nervous in origin, but they really all presented similar deformities. These deformities might appear early or late. They always reflected discredit upon somebody. Prevention of deformity was more important than its correction. The essential symptom of arthritis was limitation of movement in each direction. In view of the possibility of ankylosis, the surgeon must place the joint in a position of maximum use. Full extension was best for the hip and knee though a little flexion was no disadvantage. The ankle should be fixed to a right angle and the elbow to an angle slightly less than a right angle; the wrist should be kept hyperextended. Tuberculous deformities in the young should be corrected in the active stage, without excessive force, slowly and gently. When the deformities were fibrous in character, mechanical measures were sufficient to overcome them. More radical measures were necessary when long deformities had taken place. Bony ankylosis was rare in children. Fibrous or unsound ankylosis increased with use while bony or sound ankylosis was fixed. Tuberculosis in the young was benign and tractable; in the adult it is very different and required early and radical treatment. Manipulation, osteotomies, wedge exsections, exsections of joints, pseudoarthroses, arthroplastics, and transplantations were the procedures used for deformities in the short fibrous and osseous type. Manipulation with extension was used in young children. Osteotomy was best employed on the femur for deformities of the hip or knee and was most successful when the ankylosis is bony. Transtrochanteric section should be used if the neck was not absorbed, a wedge-shaped osteotomy being performed through the base of the trochanter if absorption has taken place, but it should be wedge-shaped to secure sufficient abduction; the operation must not be performed if the flexion was acute. Subtrochanteric division should be reserved for cases of unsound fibrous ankylosis when flexion was not very marked. In bony ankylosis of the knee, a suitable anterior wedge should be removed, the apex ending ½ inch anteriorly to the popliteal space, the remaining bone being divided by the saw. In bony ankylosis of the shoulder osteotomy of the neck should be perfomed and the arm rotated inwards and abducted forwards. Of recent years an attempt had been made to mobilize ankylosed joints. Arthroplasty entailed separation of the bones by manipulation and chisel. The bones were remodelled and covered with a flap of tissue. It was immaterial what tissue was used for the flap. It was difficult to obtain good results in the knee as the joint was largely held together by intraarticular ligaments and cartilages. Bony spinal fixation was an ideal operation in an adult with deformity of the lower lumbar region. Bone grafts were laid on the bare laminæ and covered over by muscle. Deformities of the rheumatoid or septic group once the disease had ceased were amenable to radical measures. Deformity must be anticipated, and safe and effective methods used to restore the stability and functions of the joints. Arthoplasty was useless without stability. Deformities were preventable; in view of ankylosis the joint should be fixed in a position of greatest functional use. Osteotomies and exsections of bone were rarely acquired in children. In septic and tuberculous joints the deformity could be reduced if immediately followed by fixation. Osteotomy should be performed in sound fibrous ankylosis of the hip with adduction. The site of osteotomy depended upon the nature of the ankylosis and the extent of the deformity. It should be accompanied by division of the adductors. Arthroplasty of the hip joint was often valuable and successful. It should not be performed in children or in the presence of active disease. The best results had occurred after septic cases. In osteoarthritis of the hip we now had many procedures to give relief by preventing the friction of tender joint surfaces.

Mr. C. MAX PAGE of London referred to the interesting commentary Mr. Jones' paper afforded on that read by Dr. Murphy on arthroplasty, before the Clinical Congress of American Surgeons on Monday last. He then referred to the fixation of the knee and shoulder joint in the course of tuberculous disease in those regions in children. He mentioned in relation to the knee the difficulty commonly met with in maintaining the limb in a proper position by the usual forms of splintage, and referred to an apparatus described by

himself in the January Proceedings of the Royal Society of Medicine as being useful for this purpose. In the course of tuberculosis of the shoulder joint he emphasized the importance of maintaining the arm in a position of abduction of at least 45°. He then asked Mr. Jones whether in cases of "sound" ankylosis of the hip joint in which there was little destruction of the head and neck of the bone he did not think manipulative reposition was not more satisfactory than subtrochanterie osteotomy. With respect to the shock associated with operations on the large joints he said he had found that spinal anesthesia greatly reduced it.

Mr. JOHN MARNOCH said that in arthroplasty of the elbow he had once or twice found considerable difficulty in getting sufficient fat and fascia from the neighborhood, and in his last case he took a free flap of fascia. He found this answered admirably, the flap fitted beautifully over the end of the humerus, adapting itself to the undulating articular surface, and the result was exceedingly good.

Mr. MCADAM ECCLES of London emphasized the point which Mr. Robert Jones has made as to the position in which the wrist-joint should be placed when infected by organisms, particularly by the gonococcus, namely, the position of dorsiflexion. Disease of this joint was usually treated by the general practitioner. For this reason it was necessary that the proper position should be widely known because extension or even palmar flexion was often used. The speaker suggested that in joints which had become ankylosed, in which it was desired to obtain and maintain free movement the placing of the tissues of an enlarged bursa patellae from another person between the bone surfaces should be tried. The bursa might even be used without being opened, the bursal edges being stitched to the edges of the periosteum of the bone. The line of section of the femur parallel to Poupart's ligament in ankylosed hip was approved.

Prof. J. T. J. MORRISON of Birmingham referred to the severe shock induced by operations on the upper end of the femur in elderly patients under general anesthesia, and advocated in such cases the method of spinal anesthesia by trypococaine as an effective means of preventing shock. He mentioned that Mr. Robert Jones was the first British surgeon who published his results of operations under spinal anesthesia.

Mr. J. DEC. WHEELER described a case of "cheilotomy" of the hip and knee in a girl crippled from rheumatic arthritis. The neck of the right femur was surrounded by a collar of bone causing great pain, and inhibiting movements in all directions. No weight could be borne on the limb. The knee joint on the opposite side was also the site of osseous outgrowths and was semiflexed. The girl for seven years was only able to get about with the aid of crutches, and with great pain. The ring of bone was removed from the neck of the femur through a Kocher's posterior incision and the other was similarly treated; all pain instantly disappeared, and the girl was now walking freely without crutches. The movements of the joints were normal.

Mr. HEY GROVES, and Mr. H. M. W. GRAY, also took part in the discussion.

New Appliances Used in the Operative Treatment of Fractures.—Mr. HEY GROVES of Bristol demonstrated and described these appliances. They consisted of the following: (1) The double transfixion apparatus for leg fractures, improved by the addition of a socket ¾ of an inch long exactly fitting each transfixing pin, and thus ensuring the requisite parallelism of the pins. The apparatus permitted of massage, and during the three or four weeks it was worn the patient got about on crutches. (2) Tapped plates with converging screws suitable especially for the humerus, and securing stronger fixation than was obtainable by simple plates and screws. (3) Bolted plates modified by making the nuts round, and cut like screw heads. They were tightened by a tubular screw driver and the projecting ends were cut off when firmly adjusted. (4) A new circular saw for bone work in connection with osseous grafts. It worked by means of a bevelled cog parallel with the handle or cable, and it could be carried to the bottom of a deep wound in a way not possible where the blade was at right angles to the shaft.

Mechanical Considerations of the Human Foot with Special Reference to Flat Foot.—Mr. H. S. ROWELL of Leeds read this paper.

Pott's Disease in Cervical Region, with Methods of Bony Splinting.—Mr. A. DON of Aberdeen read this paper. He briefly referred to Hibbs' method of fracturing the base of the spine above a diseased vertebra and turning it down to unite with the body of the vertebra below; and to Albee's method of splitting the spinous processes and grafting a piece of bone from the tibia. Both these methods are satisfactory in the dorsal region. The writer's method for the neck was as follows: The spines from the seventh to the second were exposed by a central incision; the seventh and under surface of the second were cleared of periosteum; a piece of rib was excised subperiosteally, and a hole drilled in the wider end so that the seventh spine could be slipped through the hole like a button, the upper end of the rib being fitted into the groove below the second spine and secured with a stitch. If the second spine was not available owing to disease, the rib was fixed to the base of the skull. He gave notes of a case in a boy of 14 successfully treated by the method described.

Friday, July 31—Third Day.

Anoci-Association, or the Evolution of the Shockless Operation.—Mr. H. M. W. GRAY of Aberdeen opened the discussion on this subject. Local anesthesia, he said, was the chief factor in the prevention of surgical shock, and general anesthetics and narcotics were merely adjuvants. Novocain in weak solutions of ¼ to ½ per cent. was non-poisonous both locally and remotely; whereas ether and chloroform injured the brain cells. Morphine prevented cerebral irritation, and was therefore preferable to general anesthetics. Prevention of mental excitement was nearly as important as prevention of pain, and was achieved by the use of sedatives. Dr. Crile's work was highly eulogized and stress laid on the procedures which were ancillary to the infiltration of tissues with novocain. The preparation of the patient should not be overdone. After the injection of an opiate it was well to cover the patient's eyes with pads and to stop his ears with moist cotton wool. Cutting instruments must be sharp, and rough handling, tearing, or pulling of tissues, especially of the peritonium and mesentery, avoided. Too hot, cold, or strong liquids readily produced shock; physiological salt solution at 100° F. usually sufficed for irrigation. Suitable clothing and warmed air were important. Hemostosis was imperative, as loss of blood might turn the scale in some cases. Proper suturing and dressings were not insignificant, and firm compression of a wound prevented effusion. The use of a general anesthetic should be dispensed with as far as possible. Ether, by the open method, might be retained, but only negligible quantities were required in combination with narcotics and local anesthesia.

In abdominal work the intercostal and lumbar nerves were blocked near the costal margins and far back in the loins, and the line of incision was also infiltrated. Five or six skin blebs were first made with a fine needle, and through the blebs injections were given by larger needles down to the peritoneum. At this stage a small amount of ether might be required. After ten to fifteen minutes the operation might be begun. Further injections might be made into the peritoneal attachments of the organs to be operated upon. The pulse rate gave a fair indication of the degree of shock. The following table showed the average pulse rate in sixty patients:

Patients	Before incision	Abdomen opened	Skin sutured	Evening after operation
With infiltration of line of incision only	89	95	94	95
With blocking of abdominal parietal nerves.....	94	87	80	85

Patients thus treated had a feeling of well-being immediately after operation; many continued sleeping for hours; others were soon able to have a meal or read a newspaper. The anesthetic solution consisted of novocain ¼ per cent., potassium sulphate 4 per cent, and twelve drops of synthetic adrenalin to 100 c.c. of solution. This compound was preferable to urea and quinine. The syringe had a capacity of 40 c.c. A Schimmel's needle was used for making the blebs, and a long strong needle in a bent nozzle for the deeper injections. If the pulse tended to flag the best restorative was a saline infusion. Transfusion of blood should be resorted to if shock threatened after an operation. In more than 2,000 abdominal sections during the last three years the author had records of only two cases of postoperative shock.

Mr. C. A. PANNETT of London restricted his remarks to the problem of preventing shock in abdominal operations. He had made an experimental investigation to measure the efficiency of Crile's technique by determin-

ing whether impulses were prevented from reaching the medullary centers. The criterion relied upon was the disappearance of vasomotor and respiratory reflexes during the manipulations. He arrived at the following conclusions: (1) Stronger impulses resulted from handling the viscera than from the incision into the abdominal wall. (2) Impulses from the viscera, therefore, more essentially required blocking. (3) In animals, impulses from the stomach could be blocked by a ¼ per cent. solution of novocain injected into the attachments of this viscus. (4) Impulses from the intestine could be similarly blocked. (5) Impulses from a middle line incision were effectively blocked by Crile's technique. Infiltration of a middle line incision lessened shock by eliminating afferent impulses; it abolished the reflex inhibition of peristalsis; and it prevented the reflex rigidity of the abdominal muscles. A serious limitation to the use of local infiltration was imposed by the presence of sepsis, for it was not permissible to risk the dissemination of organisms by thrusting the needle through infected tissues.

Mr. CUTHBERT of Gloucester had used Crile's method extensively, and he strongly supported the practice of local anesthesia.

Mr. DEC. WHEELER of Dublin thought that general anesthesia would cease to be used except in special cases or as an auxiliary to local anesthetics. Precision and gentle handling during operation were essential factors in the prevention of shock.

Mr. A. DON of Aberdeen pointed out that anoci-association not only caused blocking of impulses to the brain, but also had the merit of making an operator more gentle in his manipulations.

Mr. M. FERGUSON of Banff had employed Mr. Gray's technique for three years and was satisfied that it was preferable to Crile's method.

Prof. J. T. J. MORRISON of Birmingham called attention to the wide and increasing choice of anesthetic agents and methods available in recent years, and deprecated a too rigid adoption of one method to the exclusion of others. In particular he thought that spinal anesthesia deserved a high place in the surgeon's equipment. Compared with general anesthesia it was a preventive of shock; and compared with local anesthesia it had the merits of simplicity and time-saving, a single puncture and the injection of 20 drops of tropococaine solution inducing analgesia within three minutes. Moreover, the puncture was made remotely from the abdomen and lower limbs where the field of operation often included septic tissues which prohibited the use of local injections.

Appendicitis and Acute Appendicular Obstruction.—Mr. D. P. DALBRECK WILKIE of Edinburgh read this paper. He maintained that the most important problem at the present time in regard to acute appendicular disease was its early and accurate diagnosis. This becomes inevitably easier if we clearly distinguished between the two acute diseases to which the appendix was subject, namely, acute inflammation and acute obstruction. In cases of acute inflammation of the appendix a prompt rise of pulse and temperature was invariably present; in cases of acute obstruction of the appendix such was not the case and the local pathological changes might reach an advanced stage before the signs of inflammation supervened. He brought forward experimental evidence to show the changes which followed acute obstruction of an isolated portion of the intestine such as the appendix. The changes depended mainly on the content of the appendix at the time the obstruction occurred. The presence of fecal matter and its nature and amount largely determined the rapidity of the destructive changes which folowed obstruction. The previous diet of the animals had a very important relation to these changes, which were more rapid and of a gangrenous type in those on protein diet and slower and less fatal in those on carbohydrate diet. The prevalence of appendicitis among western nations was probably attributable to the large percentage of animal food in their dietary. The rarity of such disease in its acute and fatal form among eastern peoples was, on the other hand, probably due to the more bulky vegetarian diet which was customary among them. For the same reason acute gangrenous appendicular obstruction was more commonly met with in the male than in the female sex. Whilst immediate operation was the only safe treatment in cases both of inflammation and of acute obstruction of the appendix, it was much more urgently required in the latter; hence the importance of clearly distinguishing between the two diseases.

Therapeutic Hints.

The Treatment of Seasickness.—L. Pron outlines this treatment as follows: The diet should be light and a purgative should be taken the day before embarkation. With the onset of the attack of seasickness the patient should be placed in the Trendelenburg position and the abdomen should be firmly compressed by means of a flannel bandage. The patient should be made to take deep and frequent inspirations in order to diminish the excitability of the vomiting center. The following should be administered::

℞ Powdered nux vomica, 0.02 gram.
Extract of belladonna, 0.01 gram.
Stovaine, 0.01 gram.
Extract of hyoscyamus, 0.05 gram.

This should be given in pill form one hour before embarkation and then three times a day.

Burwinkel, regarding seasickness as the result of a vascoconstruction in the nerve centers, recommends the following:

℞ Alcoholic solution of glyceryl trinitrate, 20 drops.
Distilled water, 150 c. c.

Of this solution there should be given one to four teaspoonfuls in twenty-four hours.

One may try likewise the inhalation of five to ten drops of amyl intrite three or four times in twenty-four hours.

Naame has suggested the use of suprarenal extract in three doses of 2 milligrams each as a preventive, to be taken respectively after the last meal preceding embarkation, three hours later, and then when on board ship. Six milligrams should be taken in one dose upon the onset of an attack after the stomach has been emptied.—"Formulaire de Thérapeutique Clinique."

Charcoal in the Treatment of Membranous Enterocolitis.—A. Rodiet reports excellent results following the treatment of this usually intractable condition by means of large doses of poplar-wood charcoal. From two to four tablespoonfuls of the latter are given daily, mixed with water and administered after the midday and evening meals. The efficacy of this remedy is said to be due to its power to absorb gases from the stomach and intestine, to its antiseptic effect, and to its action in stimulating the contractility of the stomach.—*Journal de Médecine de Paris.*

Hypodermic Injections of Hexamethylentetramine in the Treatment of Typhoid Fever.—J. Baumel states that this method of treatment was first tried in 1913 by Triboulet and Levy who administered doses varying from 1 to 6 grams per day. The solutions used were sterile and were of a strength of 0.40 gram per cubic centimeter. The results were apparently quite satisfactory in twelve cases. The author employed the same method of treatment in eleven cases of typhoid fever, of which two were severe from the outset, in one case of infection with the *Bacillus paratyphosus* β, and in two cases of Malta fever. The study of these cases showed that hexamethylentetramine has no pronounced effect upon the symptoms of the above diseases, nor does it prevent complications. The treatment is apparently of value in cases of typhoid cholecystitis. The injections are painful. Small doses of 0.80 gram are no less efficacious than large doses of 4 grams.—*Bulletin Général de Thérapeutique.*

INTESTINAL INTOXICATION.

BY PROF. DR. HANS EPPINGER,
VIENNA, AUSTRIA,
ASSISTANT, FIRST MEDICAL CLINIC,
and
JACOB GUTMAN, M.D.,
BROOKLYN, NEW YORK.
PROFESSOR OF PHYSIOLOGICAL CHEMISTRY, COLLEGE OF PHARMACY, JERSEY CITY; DIRECTOR PATHOLOGICAL LABORATORY, JEWISH MATERNITY HOSPITAL; CHIEF, MEDICAL CLINIC, ST. MARK'S HOSPITAL, N. Y.

THE study of the visceral nervous system, particularly from a pharmacological viewpoint, could not long continue without some import to the clinician. With the recognition of the antagonistic position of the sympathetic division of the vegetative nervous system toward the autonomous, an attempt was made to study pharmacodynamically, also those numerous nervous phenomena caused by the terminal filaments of the vegetative nervous system and not directly by the organs enclosing them.

With the above in view, Eppinger and Hess succeeded in separating from the great number of intestinal neuroses an independent pathological condition, the vagotony. By the aid of exact pharmacological examinations and by various other means they were able to demonstrate that of the two antagonists constituting the visceral nervous system, the one, the autonomous division, is much more sensitive and more readily responsive to irritation than the other, the sympathetic: so that even the normally mildest of physiological stimulations affecting the first suffice to disturb the equilibrium maintained by the two opposing forces.

It must especially be emphasized that a high tonus of the entire autonomous system is not of frequent occurrence. On the other hand, varying increments of irritability of individual branches of the system are a common concomitant of pathological conditions. While studying the various features of a case the pathogenic element may very frequently appear preeminently conspicuous and seem of such importance as to apparently overshadow the others (as, for instance, in vagotony-intoxication by vagus irritants); but, in our opinion, even the purely nominal division or classification of the individual symptoms into autonomous and sympathetic, in itself constitutes a marked advance for the clinic, and is of as much importance as the pathogenic element. That this classification is of considerable practical value may be seen from the circumstance that we are enabled by the help of irrelevant drugs such as atropine, pilocarpine, etc., to differentiate between depression and irritation of the diametrically opposed nervous systems, a distinction often invaluable in the direction of rational therapy.

*From the First Medical Clinic, Prof. von Noorden, Vienna, Austria.

Reviewing the various phenomena associated with disease we may soon observe that symptoms characteristic of severe general vagus irritation occur in most cases of meat or sausage poisonings. Such symptoms as bradycardia, low blood pressure, diarrhea, discharge of mucus from the lower bowel, vomiting, profuse sweating, salivation, frequently eosinophilia, spasm of the ciliary bodies, contraction of the pupils, etc., are commonly associated with the above mentioned conditions. Even to the layman such a succession of symptoms, especially if sudden in appearance, suggests the idea of poisoning.

But such violent disturbances as enumerated above, and similar to those resulting from pilocarpine poisoning, are not limited to injuries effected in the intestines by poisons introduced from without, but may also be produced by substances originating within the intestinal tract. We see this fact most clearly illustrated when considering the symptomatology of spastic constipation and its numerous complications. The close relationship between general intoxication and intestinal derangement is very plainly exemplified in those cases and can easily be verified: the proper relief from constipation will be followed by a total disappearance of all the symptoms of autonomous irritation which it caused, such as hyperacidity, hypermotility, spasms of the stomach, bradycardia, extrasystoles, etc.

The organs controlled by the terminals of both visceral nervous systems are held in readiness for contraction or relaxation. Between these two extreme states there exists an intermediate one, a state of equilibrium, a normal tone, which is dependent upon the tonic innervation of the autonomous nervous system on the one hand and of the sympathetic on the other. The force controlling the latter, the sympathetic system, is known; it is suprarenal extract. But the substance affecting the stimulation of the former system, the autonomous, is as yet unknown. However, it is very logical to assume the existence of such a body or hormone. Knowing that suprarenal extract originates in an organ capable of internal secretion, we had hoped to discover the vagotropic hormone in one of the other glands of similar function. Notwithstanding numerous attempts to detect the source of a vagotropic hormone we have met with no success. Because of the frequently simultaneous occurrence of vagotony and status thymicus we were inclined to assume the thymus as the source of origin of a vagotropic secretion, but, we must admit, without any substantial ground other than the one specified. Because of failure with glandular organs it became necessary to search for the hormone controlling the autonomous system in other parts of the organism. For this reason we turned our attention to the intestinal tract.

Barger and Dale, during their investigations of

the physiological properties of the ergot preparations have isolated from ergotoxin, which is probably composed of a number of substances, a singular body, the so-called beta-imidazolylethylamine. This body is an amino-acid-base apparently identical with histidin, a product of protein decomposition and of putrefaction. Beta-imidazolylethylamine, also called histamin, causes a number of disturbances very similar to those following the application of poisons known to be typical irritants of the autonomous system. In most animals the intravenous injection of histamin produces a depression of the blood pressure of the general circulation and a simultaneous increase of blood pressure in the pulmonary artery, a phenomenon probably brought about by the dilatation of the blood vessels of the peripheral organs. Furthermore, histamin produces spasm of the bronchial musculature, bradycardia, contraction of the virgin and non-gravid uterus, salivation, lacrymation, etc. As these symptoms may be controlled by atropine, which is a typical vagus depressant, it might have been concluded that histamin effecting them would have to be placed in the category of vagus stimulants; but such a conclusion would have been erroneous as the activity of histamin differs from that of the latter in many respects. For instance, it is known that certain doses of suprarenal extract usually producing typical blood pressure elevation in the presence of histamin not only fail to accomplish this, but react altogether differently, being actually attended by a fall in blood pressure. The irritation of the splanchnic nerves in the presence of histamin also leads to a depression of instead of an elevation in blood pressure. Only barium chloride and hypophyseal extract, which is believed to influence the smooth muscle fiber directly, effect that circulatory system with an increase in its pressure. It may be assumed, therefore, that the point of attack of histamin is not the same as that of pilocarpine or muscarine, but is confined to the myoneural zone exclusively.

Barger and Dale were able to isolate still another base from ergotin, a substance known as para-oxyphenylethylamine. This body, also named tyramin, is derived from the decomposition of tyrosin. In its chemical properties it possesses certain very definite similarities with suprarenal extract and in common with the latter, also a number of functional characteristics. Dale and Dixon have demonstrated the physiological relationship between tyramin and suprarenal extract; these two differ, according to von Knaffl-Lentz and Pick, only in their mode of attack, the suprarenal extract acting upon the central nervous system.

The discovery that such violently active poisons as beta-imidazolylethylamine and para-oxyphenylethylamine, originating during putrefaction and therefore playing an important rôle in the intestinal tract, are closely related to proteins, became of great value to the pathologist. But the fact that Barger and Dale have actually isolated histamin from normal (although not living) intestinal mucosa commanded even greater attention. These two English investigators have assumed also the substance which Popielsky had isolated from the intestinal mucosa, secretin, to be identical with histamin. Up to the present time, it has been possible to obtain from the mucous membranes of the intestines only histamin; however, no mistake would be made to assume the generation of other bases during the decomposition of the great variety of amino-acids in the process of putrefaction. Remembering that practically all bases are extremely active substances, some of which hardly differ in their intensity from adrenalin, and bearing in mind also that many of these basic substances are active irritants of the entire autonomous system, it seems justifiable to pay closer attention to those found in the intestinal tract under physiological and pathological circumstances.

The information that bases are to be found in the feces of man is not of recent acquisition. Baumann and Udransky were able to demonstrate the presence of putrescin and cadaverin in the stool of one of their patients, a case of cystinuria. Both cadaverin and putrescin are bases and products of protein decomposition. Cadaverin is a derivative of the amino-acid lysin, while putrescin finds its origin in diaminovalerianic acid. Roos was able to prove the existence of these substances also in diarrheal stools of non-cystinurics. To the writers of this paper, who are concerned only with the pharmacological action of the various bases, putrescin and cadaverin are of lesser interest and especially so since these bases when injected in small doses intravenously produce but little toxicity. The statement of Glaessner that he had been able to prove the presence of oxyphenylethylamine in the stools also deserves attention. With this information our total knowledge concerning the existence and functions of the bases in feces is practically summarized. It became, therefore, our intention to further investigate the characteristics and significance of amino-acid bases found in the stools of both normal and abnormal individuals.

Because of the enormous difficulties of the isolation from feces of individual bases we decided to confine ourselves at the beginning of our investigations to general, even if rougher figures, *i.e.* to the investigation of groups consisting of chemically related substances and not of separate bases. With this in view it seemed advisable for our purposes to make use of the method of Hausmann and Pfaundler. This method is devised for the purpose of separating the total nitrogen of urine into divisions consisting of substances similar in their constitution. For our purpose it seemed to promise the best results, but being adapted for the examination of urine only, it was first necessary to modify it so as to make it practicable also for that of feces.

In the first place we kept the patient whenever possible and compatible with the general treatment upon a definitely standardized diet. Only in those cases where some special object was to be obtained a deviation from the prescribed diet was permitted. Whenever this was done it will be specified in the following pages, as for instance, a cellulose-rich diet or a protein-rich diet, etc.

The patient's stools, generally comprising the daily output (to the actual quantity we paid no attention as the only information sought was the percentage of nitrogen distribution and not the actual quantity) were macerated, ground into a very fine mass and enough 3 per cent. hydrochloric acid added to make up the total quantity to one liter. The mixture was then placed upon a water bath and heated until it became perfectly uniform; distilled water was then added to prevent too strong concentration from evaporation. After full digestion the mixture was removed from the water bath and filtered; to the residue enough hydrochloric acid was added to bring the volume to one liter. This fluid was again thoroughly digested by heat-

ing over the water bath, then filtered, and this filtrate added to the one previously obtained. The last residue was similarly treated as the two former. The filtrate derived from the last extraction was added to those previously obtained. The combined filtrates constituted the standard solution employed in the analyses, but before using it for such purpose the last residue was tested for possible traces of nitrogenous material. Usually after such vigorous treatment and in the manner above described, the residue of the feces when tested by the Kjeldahl method contained none, or if present, the amounts of nitrogen were negligible; in but few instances did we find it necessary to repeat the extraction once or twice more.

To the protein nitrogen sometimes present in feces very little attention was paid as in our investigations the amounts of base-N only were of interest to us. However, if at all present as a result of the digestion of the stools with the hydrochloric acid the peptones and albumoses must have been converted into amino-acids. If such conversion actually did take place and the nitrogen in consequence thereof suffered a rearrangement in distribution, then it could have only resulted in favor of the amino-acid group and that only.

The total fluid acid extract prepared in the manner previously described was employed as a standard solution of the feces it was obtained from and analyzed according to the prescribed method of Hausmann and Pfaundler for urine. Twenty c.c. of the fecal extract were mixed with 40 c.c. of a 10 per cent. phosphotungstic-hydrochloric acid solution (100 c.c. of phosphotungstic acid, 100 c.c. of hydrochloric acid, 800 c.c. water). The precipitated mixture was allowed to stand for 24 hours in an atmosphere free from ammonia. It was then filtered into Erlenmeyer flasks through nitrogen free filter paper, the residue on the paper being washed several times with the filtrate and the above acid mixture. Then precipitate and filter paper were placed into similar Erlenmeyer flasks and water in amounts equal to that of the filtrate in the other flasks was then added. Into each of the flasks 10 grams of crystallized phosphoric acid was then placed and all of them put into an oven for 18 hours at a constant temperature of 150° C. While there care was taken to avoid too vigorous ebullition. At the end of the prescribed time the flasks were removed from the oven and after cooling their charred contents were thoroughly dissolved by the addition of hot water.

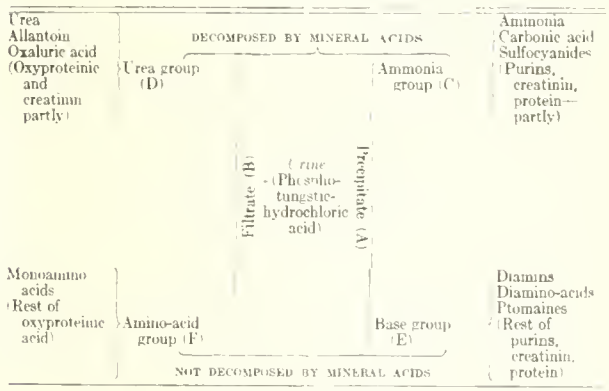
These solutions, the remainders of the former precipitates and filtrates, were then poured into large distilling flasks and carefully neutralized with a solution of sodium hydroxide, using litmus as an indicator. Enough calcined magnesia was then added until the solutions were strongly alkaline in reaction. The flasks were then connected with condensers and their contents distilled over, using a N 4 sulphuric acid solution in the nitrogen receiver. Care was taken to obtain complete distillation of the ammonia. For this reason the residue remaining after the first distillation was diluted with water and redistilled, using a fresh portion of acid solution in the nitrometer. Usually a trace of additional nitrogen was thus received and added to that of the previous distillate, obtaining thus the correct total nitrogen contents of the distilled fluids. These figures when subtracted from the corresponding amounts of total nitrogen contained in equal portions of precipitate or filtrate and determined in the ordinary manner by Kjeldahlization gave the nitrogen values unaffected by the magnesia neutralization.

We have thus investigated the following groups and obtained the following figures: (1) The total-N in 20 c.c. of the original total extract of the feces of an individual and obtained by the usual Kjeldahl method; (2) The total nitrogen of the precipitate obtained after treating 20 c.c. of the above extract with the phosphotungstic-hydrochloric mixture (A); (3) The total-N in the filtrate obtained in the above manner (B); (4) The total-N obtained from distillation of the precipitate, using the calcined magnesia after previous oxidation in the oven with phosphoric acid (C), ammonia group. (5) Total-N of the distilled filtrate obtained in the same manner as the above precipitate (D), urea group; (6) Subtracting the amounts of (5) from those of (3) gave the total nitrogen of those substances not affected by the magnesia distillation, (F) amino-acid group; (7) Subtracting the findings of (4) from (2) gave the same variety of nitrogenous substances contained in the precipitate (E) base group.

It may be well to add here that each test performed was accompanied by one or two controls and the averages obtained from tests and controls were thus recorded.

The composition of the four groups into which the various nitrogenous substances of the urine are classified may best be illustrated by the following diagram:

TABLE I



Before we begin the description of our investigations we desire to mention the fact that Glaessner had also given his attention to the nitrogenous distribution in stools, but in his analyses he confined himself exclusively to the nitrogen derived from coagulable and noncoagulable substances and to that precipitated by phosphotungstic acid. His reports we shall analyze and compare with ours later.

In table II we present the results obtained from our examinations of normal stools. We defined stools as normal if passed daily at the same hour, and by individuals apparently in good health. By "mixed diet" in the column so headed we understand an ordinary dietary used by the average person. Under "oats" is meant the Schmidt-Strassburger test meal (with meat). The figures in the different columns under the various headings express the number of cubic centimeters of N 4 HCl necessary for the neutralization of the ammonia distilled over after oxidation of the corresponding substance in the ordinary Kjeldahl manner. To the actual amounts of nitrogen per diem we paid no attention; only the relative proportions into which the

nitrogen is distributed did we take into consideration.

TABLE II

No.	Disease	Diet	Total N.	Phosphotungstic		Ammonia, N.	Base, N	Urea, N.	Amino-acid, N.	Percentages			
				Precipitate	Filtrate					Ammonia N.	Base, N	Urea, N.	Amino-acid, N.
1	Normal	Mixed	35.5	19.5	15.5	19	0.5	15	0.5	54	1.4	43	1.4
2	Normal	Oats	16.5	10	6.25	9.75	0.25	6	0.25	58	1.5	36.4	1.5
3	Normal	Mixed	43	27.5	15.5	22	5.5	14	1.5	51.1	12.8	32.6	3.5
4	Normal	Mixed	45.5	28	17.5	19	9	15	2.5	41.7	19.8	33	8.5
	Averages									51.2	8.9	38.2	3.7

In studying table II, particularly as to its percentage figures, it soon becomes evident (1) that about half of the nitrogen in normal excretions is in the form of ammonia, while (2) the smallest amount is found in the amino-acid group, (3) the relatively least variations, *i.e.* the greatest uniformity in quantities is found in the urea column, (4) the base-N figures which claim our greatest interest are peculiar, in that in two groups of normal individuals they were very low, while in the other two, also representing healthy persons, the figures obtained were high, in fact, nearly as high as those later observed in pathological cases; hence, the average of the base-N obtained for normal individuals.

Let us first describe very briefly the cases employed in our investigations and presented in above table:

Case I.—This case, one of so-called dysentery, was that of a woman who had suffered for many months from diarrhea and at times fever and vomiting. The patient was very emaciated and anemic. She passed daily five to ten watery stools from which several varieties of bacilli of the paratyphus group were cultivated. True dysentery bacilli and amebæ were not discovered. The diarrhea was not controllable by medication. Proctoscopically, a number of small ulcerations were visible in the lower bowel. An operation for colostomy was performed and affected exceptionally favorably the course of the disease. The stools always reacted alkaline to litmus and practically constantly contained blood. Microscopically, there were very few food-rests, numerous red blood cells, few white, but a great number of bacteria. Sections when stained showed a preponderance of gram positive bacteria over gram negative.

Case II.—Enteritis. This patient was suffering for a number of days previous to her admission to the clinic from gastrointestinal disturbances, caused by the ingestion of contaminated meat. In the beginning she had fever, vomiting, and headaches; later these symptoms gradually improved but the diarrhea persisted. She passed from five to six thin watery, ill-smelling stools, containing considerable mucus. Bacteriologically, the paratyphus *B. bacillus* was isolated. Chemically, blood was found. Upon thorough calomel treatment a cure was effected.

Case III.—Represents a typical form of tubercular enteritis complicating extensive tuberculous involvement of the lungs. This man had from eight to fifteen thin stools daily; they were usually alkaline in reaction considerably intermixed with blood, and rich in mucus. At the autopsy, extensive ulcerations distributed all over the surface of the small intestines were found, and in addition, partial destruction of certain segments of the colon.

Case IV.—This case was that of a woman 38 years old, who had suffered for some time from pain in the abdomen. She also complained of fever, headaches, and diarrhea. The passages, four to five daily, consisted of mucoid like substances enclosed in semi-solid masses. Their reaction was strongly alkaline. Microscopically, the stools contained numerous bacilli, very few formed elements, some blood, and a number of leucocytes and eosinophiles. Proctoscopically, the mucous membrane of the rectum was much reddened and thickened. Upon treatment with atropine and a special rough diet the diarrhea ceased. It was not possible in this case to isolate the particular bacterium, the cause of the affection.

TABLE III

No.	Disease	Diet	Total N.	Phosphotungstic		Ammonia, N.	Base, N.	Urea, N.	Amino Acid, N	Percentages			
				Precipitate	Filtrate					Ammonia N.	Base, N.	Urea, N.	Amino Acid, N.
1	A. Dysentery	Meat	96	63.5	32.5	47	16.5	31	1.5	49	17.1	32.3	1.6
2	Dysentery	Carbohydrate	99	56	43	31.5	24.5	37.5	3.9	31.8	24.7	37.8	5.6
3	B. Enteritis	Meat	15.5	9.5	6	8.5	1.0	5	1	55	6.3	32.4	6.3
4	Enteritis	Carbohydrate	25.0	15.5	9.5	7.5	8	8	1.5	30	32	32	6
5	C. Enteritis tuberculosa	Mixed	173	139	34	91.5	47.5	31	3	52.9	27.4	18	1.7
6	D. Cystitis and proctitis	Mixed	87	59.5	27	52.5	7	24.5	2.5	60	8.4	28.1	3.5
7	Cystitis and proctitis	Meat	108	76	32	59	17	28	4	54.9	15.8	26	3.6
8	Cystitis and proctitis	Carbohydrate	42	26	16	19	7	14	5	45.2	16.7	33.8	4.8
	Averages									49.8	18.4	31.25	4.14

Examining the above table for its percentages of base-N we are soon impressed with the decided increase in the size of the figures, the average in the pathological cases being nearly twice as great as in the normal ones. The ammonia values do not materially differ from those of normal cases, but the urea quotient is somewhat diminished. That the increase of base-N occurs at the expense of the urea component is the only possible conclusion that we can draw. The amino-acids show only a very moderate increase. Examining the cases individually, we must conclude that a decided increase of the basic-N is very common to diarrheal diseases especially if the stools are of an alkaline reaction.

One explanation though must be made, in the cases of Table III. Here the dietary was quite frequently changed abruptly. Most of the patients were kept on one diet for two consecutive days and then suddenly placed on another of an entirely different composition. For the examinations the stools of the second day were utilized. This explanation is very necessary as the base-N is very appreciably increased with each abrupt change in the qualities of a dietary as proved by our previous experimentations. This increase occurs in normal as well as in pathological cases but with the following difference: in the former the figures reach their previous dimensions very rapidly while in patho-

logical cases only very slowly. We made this observation in all our previous experiments and those cited below, a fact especially important to bear in mind when studying Table III. In order to demonstrate this statement the following table is presented:

TABLE IV

No.	Date	Disease	Diet	Total N	Phosphotungstic		Ammonia, N.	Base, N.	Urea, N.	Amino Acid, N.	Percentages			
					Precipitate	Filtrate					Ammonia, N.	Base, N.	Urea, N.	Amino Acid, N.

9	11/6	Chronic enteritis	Carbohydrate	87 3	52 2	35 1	31.2	21	28 8	6 3	35 7	25	32 2	7 1
10	12/6	Chronic enteritis	Carbohydrate	120	69 1	51	49 1	20	42.7	8 3	40.7	16 9	35 6	6 8
11	13/6	Chronic enteritis	Protein	80	60 7	20	30.4	30.3	16.3	3 7	37.8	38	20 2	4
12	14/6	Chronic enteritis	Protein	88 6	56 2	32 5	22 5	23 7	23 6	8 9	36 8	27	26 2	10

The case marked "normal" was that of a female nurse of our hospital. The case "chronic enteritis" was that of a male suffering for some time with nontuberculous diarrhea. Rectoscopically, there were no ulcers in his sigmoid flexure, but in the feces paratyphus *B. bacilli* were present. The patient was relieved by temporary colostomy and local applications.

The above table clearly shows the great increase in the amount of base-N occurring with each abrupt change of food, and it demonstrates the necessity of permitting the patient to accustom himself to each dietary before sampling his feces for analysis. Otherwise too high values, hence erroneous, may be obtained.

For the purpose of determining the relationship between the severity of the symptoms of a disease and the quantity of base-N excreted in the feces of the affected individual, it might perhaps be advisable to study first the symptomatology of the cases in question (Table V) and to compare them with the obtained figures of base nitrogen contained in their feces.

TABLE V

	Average percentages									48 8	18 2	29 6	3.8

Case V.—This was a case of carcinoma of the rectum with partial stenosis of the gut and numerous metastases in the liver. Patient had one or two normal appearing stools, but which upon chemical analysis were found to contain blood. The cachexia was of a rapid and progressive type and death ensued therefrom. The autopsy revealed the above mentioned pathological lesions.

Case VI.—This case, also ending in exitus, was that of a patient with a large tumor in the region of the cardia of the stomach. Hematemesis was frequent and very considerable. The woman was very anemic and suffered from most obstinate constipation. She practically never had a voluntary passage, and had to resort always to enemas and cathartics to induce a movement of the bowels.

Case VII.—This case resembled very much one of true typhus abdominalis but the blood agglutinated only the *Bacillus paratyphosus B.* The disease was probably caused by sausage poisoning. Patient was kept on a milk diet and thus cured. Stools: one daily of normal formation.

Case VIII.—In this case the disease began with vomiting, diarrhea, and other gastrointestinal symptoms, but very soon these were followed by jaundice. The biliary ducts seemed to have been completely occluded as the patient's feces were devoid of bile. She passed daily one or two stools and those obtained during the above mentioned stage, that of jaundice, were used for the analyses.

Case IX.—This represented a typical and very severe form of juvenile tetany. The attack which compelled the patient to seek the aid of our clinic, was his third, the other two having occurred in the two previous years of his life. He had one passage daily, of normal formation and with the exception of a slight amount of mucus also of normal constitution.

Cases X and XI.—These were typical cases of spastic constipation occurring in individuals of a distinct vagotonic type. Both patients (ages 27 and 30, respectively), had applied to the clinic because of stomach discomfort and hyperacidity. Spontaneous evacuations from the bowels were to them impossible for years; only with the help of enemata and cathartics were they able to clear the bowel from its contents and to obtain the desired relief. During such periods of constipation they suffered from headaches, sensations of heart palpitation, and frequently also vomiting. When placed upon a Schrot diet their conditions improved very rapidly, and their complaints soon ceased.

Case XII.—Was that of a woman 60 years old who was struck with a very severe hemorrhage of the stomach. For eight days food had to be entirely withheld from the stomach; at the end of that period feeding by mouth was only permitted in the form of tablespoonful doses of milk. The stool samples were taken at this stage of the disease, when the patient was nourished in

the form of hourly portions of milk. The presence of carcinoma was fairly excluded by subsequent examinations after the patient had fully recuperated.

Having now briefly described the cases under observation, and before beginning the analyses, we wish to mention that use has been made from the experience derived from the experimentations in the cases enumerated in Table IV. Hence, their analyses were undertaken only several days after a certain diet had been administered and only after the patient had evidently accustomed himself to such diet. This rule was rigidly observed in cases of spastic constipation and tetany.

It might have been very interesting to make a study of every division of nitrogen distribution in feces, but at present we had to confine the scope of our investigations to the base variety exclusively. It seems remarkable that the lowest values of nitrogen shown in the above table (Table V) were found to be associated with cases kept on an exclusive milk diet, one of inanition (Case XII) and another of paratyphus (Case VII). It proves, therefore, as far as may be concluded from these experiments, the favorable influence which a milk diet may exercise upon the amount of base-N in the stools of those exclusively so fed. The inanition case exhibited also the greatest quantity of ammonia-N. Rather high amounts of base-N were found with both carcinomata, intestinal and cardiac. Biliary stasis, as far as may be judged from the one case on hand, had no exceptionally pernicious influence upon the base-N; for figures in the neighborhood of 14.9 per cent. are far below those obtained in enteritis cases without biliary stasis.

Very interesting results were obtained in the cases of spastic constipation and vagotony. At least one of these, Case XI, deserves our particular attention. In this case the Schrot diet had exercised a very decided effect upon the whole course of the disease, while the figures of base-N were the highest ever obtained, much higher than those derived after the administration of carbohydrate or protein diets. At this time it is but fair to add that while the Schrot diet relieved the patients from the constipation and its accompanying disturbances the other two, *i.e.* the carbohydrate and protein diets had no such favorable effect; on the contrary, all complaints previously removed by the Schrot diet, with the administration of the other two had returned. In the other case of spastic constipation (Case X) 20.9 per cent of Base-N was obtained during the period of Schrot dieting; during that of meat, 17.4 per cent., and upon the use of carbohydrates as high as 23.6 per cent. of base-N. It should also be added that during the periods of carbohydrate and protein feedings, there was a tendency to diarrhea rather than constipation.

In the case of tetany, although free from any stomach or intestinal disturbances, the highest values of base-N that had ever come to our attention have been observed. In but one other case, that of enteritis, a severe inflammatory condition, (Table IV No. 11), was the percentage anywhere near as high as that of tetany, the figures in the former case having attained upon an abrupt change of the dietary the maximum values of 38 per cent.

Although we have not presented very many cases of intestinal derangement, still we believe to be more or less justified in drawing conclusions on the subject of intestinal intoxication. At first we shall consider the question whether any intimate relationship exists between the severity of the symptoms of a given individual and the amount of aminoacid bases present in his stools. If we carefully peruse the figures exhibited in our tables, and compare these with the severity of symptoms of the cases they were obtained from, we may soon arrive at definite conclusions. Let us, for instance, compare the case of dysentery of Table III, an exceptionally severe intestinal disturbance, showing base-N values of 17.1 per cent. to 24.7 per cent. with that of a normal individual such as Case I of Table II and base-N values of 19.8 per cent. From this it may be concluded that there is practically no relationship between the amount of base-N and the severity of the symptoms. However, it is very singular that a normal individual absolutely free from intestinal or other disease should nevertheless excrete as much base-N as that encountered in conditions of most extensive intestinal disease, severe inanition, or general prostration. But neither are striking differences in the amounts of base-N to be found in the examination of the other cases under observation of extremes of pathological conditions; so that we may be justified to conclude that no particular difference exists in the amounts of base-N of normal cases and that of pathological cases. Were we still to adhere to the hypothesis that the characteristics and severity of symptoms of a disease are indirect in proportion to the quantity of aminoacid bases, excreted in the feces, then we must assume the existence in the intestines of protective agencies whose function it is either to qualify or to counteract in varying degrees the toxic effects of the intestinal contents. Such qualifications if present might correctly be ascribed to a properly functionating intestinal mucosa and to the normal activity of the liver.

Any probable inaccuracies of the figures exhibited in the various tables must be ascribed to the Hausmann-Pfaundler method for separation of nitrogenous substances into related groups by precipitation with phosphotungstic acid. While this method is known for its exactness, yet there is no positive evidence that all the so-called base-N obtained by it belongs exclusively to the class of aminoacids. In our former investigations dealing with fractional separation of nitrogenous substances of fluids, we have shown that the base fraction particularly consisted not only of precipitated ptomaines and diamines, but also included the diaminoacids, and partly purins and creatinine. Because of the greatly complicated technique, the identification of individual bases in each of the cases was impractical if not impossible. We confined ourselves, therefore, to the isolation of separate bases in but a few of the cases. Substantial quantities were obtained only in pathological cases. As already mentioned, Roos isolated from pathological stools, cadaverin and putrescin, while Glaesner discovered oxyphenylethylamine. We should like to call attention herewith to two other bases, which we were able to detect in the feces; one, phenylethylamine, characterized by its presence in stools independent from the variety of food ingested; the other, evidently betaimidazolylethylamine, of especial significance because of its unusual toxicity.

For the separation of individual bases, we used the method of Kutscher, modified, however, so as to be applicable for stool examinations. To prepare the solutions, the stools were mixed with hydrochloric acid. This mixture was then concentrated to one-third its volume. To the rather voluminous

remainder (we utilized for each such test a ten days' quantity of stools) phosphotungstic acid was added until a test sample upon the addition of the above acid remained clear for one minute. The mixture was then allowed to settle for twenty-four hours, filtered, and the precipitate washed with 5 per cent. sulphuric acid until free from chlorides. It was then washed free from the filtrate with hot water, treated with hot barium solutions under the usual precautions and washed several times by boiling it with hot water. The remaining fluid was then treated in the manner prescribed by Kutscher for the determination of organic bases in urine.

What concerned us most were the silver precipitations II and III. In spite of very careful analyses and valuable assistance obtained from eminent consulting chemists of the clinic, we were not successful in obtaining substances in quantities sufficient for analysis of more complicated structure than the relatively simple bases methylamin, putrescin, cadaverin, etc. We then made an attempt to artificially create more favorable conditions for the appearance of the desired bases in feces by feeding one normal individual and one with intestinal disease with the aminoacids phenylalanin and histidin. We administered to them daily for one to two weeks ten grams of phenylalanin and 4-5 grams of histidin, so that they received during that period about 70 grams of phenylalanin and 25 to 30 grams of histidin. Only after such a procedure were we successful in isolating from the stools of the pathological as well as the normal individual the substances desired (phenylethylamine and imidazolylethylamine); partly in the form of picrates and partly as platinates. It must here be added that the quantity obtained from the feces of the normal case was considerably smaller than that of the pathological.

For the detection of betaimidazolylethylamine, even in smallest quantities, and to demonstrate also at the same time its pathogenic properties, we discovered a method by which these objects might be easily accomplished. If the human skin be very superficially scratched with a needle so that the uppermost layer of epithelium is denuded and if a drop or two of betaimidazolylethylamine in a solution of 1 to 1,000 be applied to it, within five minutes a typical reaction appears at the point of application. The skin turns very perceptibly pale and becomes somewhat elevated above the rest of the surface. Then this pale and projecting swelling begins to increase rapidly in width and height, reaching its maximum in about four or five minutes, at this same time retaining exactly the shape of the original scratch mark although the mark itself entirely disappears. In some individuals the swelling has been observed to reach a width of 3 cm. and a height of 2 mm. The whole reaction has very much the appearance of urticaria, even as to its characteristic subjective symptom, the itching which accompanies it. Imidazolylethylamine is recommended as an ergot substitute for the control of uterine hemmorhage. For this reason we made use of it in one of our cases of uterine bleeding, but we decided since then never to employ it again for such purpose as the untoward effects produced by it are undesirable. Immediately after the injection of the drug the patient's body turned scarlet red and in some places, such as the face, quite cyanotic, but the redness would disappear when the skin was pressed upon. Other severe or serious subjective symptoms were absent. We have experimented with a great number of other bases but no other substance than the one mentioned, betaimidazolylethylamine, was found to react in the manner described, so that we concluded the reaction to be specific for that poison. This qualitative test was later used for the identification of histamin in the analyses of the other stools. If this test is really specific for imidazolylethylamine, then its presence in the stools of all normal individuals might be assumed with reasonable certainty, for at least in one normal case have we been able to isolate the above substance beyond any doubt. This fact seems to deserve emphasis.

Because of the striking similarity of the symptoms of true urticaria and those of imidazolylethylamine poisoning, it appeared to us logical to suspect the poison in the stools of those habitually suffering with urticaria. But we were disappointed to find in two exceptionally typical cases of this condition examined with the above object in view no appreciable differences from that of the normal.

In animals, histamin produces also a combination of symptoms very similar to that of bronchial asthma of human beings. Assuming the possibility of some connection between asthma and histamin we made an attempt to look for the latter in the stools of several cases of bronchial asthma; but again as in the cases of urticaria, have we failed in our mission and could find nothing particularly abnormal. Notwithstanding these disappointments we still remained clinging to the presumption that the symptomatology of the two above mentioned diseases is caused by some derivative of protein decomposition; therefore, we decided to place our patients with habitual urticaria upon a diet as protein-free as was possible. In a number of instances we obtained indeed very satisfactory results, but when the same method was applied to asthma cases it had no influence upon their attacks.

The facts established that bases originate during the decomposition and putrefaction of organic matter and that differentiated amino-acid-bases are produced by bacteria in pure culture form, suggested the idea to ascribe the origin of the poisons discovered by us in the intestinal canal, also to bacterial activity. This presumption was further strengthened by the recent discoveries of Mellanby and Twost. These two investigators were able to cultivate from the intestines a bacillus possessing the power to convert histamin into imidazolylethylamine. Furthermore, they proved that this bacillus can accomplish this act in an alkaline medium only, while the addition of acids or sugars seems to create surroundings unfavorable for the bacillary production of the base. This fact may serve as additional proof in our argumentation.

The demands from the clinic and the bacteriological laboratory for practical applications of these important discoveries are numerous. Should it be definitely proven that many of the bases are of vital importance to the economy of the animal organism, then such proof would constitute additional evidence for the necessary symbiosis of bacteria and the animal organism. We also considered this question from another point of view: whether these bases originating within the intestinal canal and having properties similar to the hormones of the secretory system are not substances distributed to the organism to exert their influence upon the vegetative system. Experimental pathology has already utilized this principle by employing histamin to antagonize adrenalin. It may with reasonable

certainty also be assumed that histamin is not the only base formed in the intestines, but that numerous others originate there. Besides it is quite plausible to connect the absorption of these very active poisons originating during intestinal derangement with the symptomatology of the intoxication accompanying the same. While we have not been able to treat the whole subject under consideration as completely as we would have liked to do, yet we believe we have been able to prove with reasonable certainty the presence under pathological as well as physiological conditions of poisonous amino-acid-bases and to a certain degree their importance. If these bases really do play such an important rôle in the human organism even the normal, then we must ascribe as powerful a command to the intestinal canal upon the general circulation as to a gland with internal secretion. We have no desire for chimerical assumption of hyper- or hypofunction of the intestinal organs, but what we wish is to impress the fact that amino-acid cases do exist in the lower bowel and that their elimination is brought about in the feces.

THE STERILIZATION OF MENTAL DEFECTIVES CONSIDERED FROM THE PHYSIOLOGICAL STANDPOINT

By AMOS W. PETERS, PH.D.,

VINELAND, N. J.

(From the Department of Research of the Training School at Vineland, N. J.)

The removal of the power of procreation from all mental defectives by some form of surgical operation has been much advocated as a means of relieving organized society of one of its serious burdens. This agitation has borne fruit in the enactment of legislation in various States, but thus far at least has practically ceased to progress further than the stage of placing such laws upon the statute books. The adequate and necessarily extensive enforcement of these laws so as to give success to the plan of sterilization as a large social relief measure does not seem to be in prospect. In all probability this method of dealing with the problem as a whole is destined to fail so far as the near future is concerned and to be replaced by other measures, the practical enforcement of which cannot encounter the aversion of the public. Wholesale sterilization as a relief measure is a practical question involving something to be done, and if there are inherent in it factors which lead to its ultimate neglect, whether these factors are logically justifiable or not, then this measure becomes a failure. That such factors are operative is evidenced by the neglect of the practical enforcement of sterilization laws. Among these factors we believe the following two stand out prominently. First, no doubt, as the mind of the public conceives it, is the removal from the human body of a normal organ by a surgical operation, *e.g.* castration. Second, perhaps, is the ultimate realization of the large number of individuals in every State who would have to be pursued outside of the institutional population in order to make the measure efficient against the increase of the defective. The present discussion is not concerned with the occasional resort to sterilization in exceptional cases, but with sterilization as a State measure, firstly, for a large part of the institutional population, and secondly, if conditions would permit, for a large part of the non-institutional defective population which will probably always exist. The agitation for sterilization from these viewpoints would appeal to the public more effectively as judged by the result of practical enforcement if the procedures to be used were of a less radical nature. If a surgical operation, *e.g.* castration, which a large portion of the public mind considers to be mutilative, could be abandoned, or if a lesser operation, *e.g.* vasectomy, could be substituted therefor, or, still better, if a non-surgical procedure, *e.g.* Roentgenization, could be used, these more moderate measures would more readily receive public approval and enforcement.

The problem of sterilization thus presents two main aspects which are respectively sociological and physiological. As judged from the former standpoint, it is taken for granted in the present discussion that sterilization ought to be practised with certain defined classes of defectives. With reference to the motive for this procedure we differ with many in holding that a proper sociological motive therefor is primarily and only the removal of the power of procreation from designated individuals. Sterilization simply to prevent masturbation is not justified by our present knowledge on the subject of masturbation itself. Castration for the purpose of preventing masturbation seems to be a highly questionable procedure in view of the psysiological factors involved.

In the present state of our knowledge there are three chief methods of sterilization available. Two of these are fairly well known and are more or less commonly advocated. These are first the removal of the sexual glands in either sex (castration, ovariotomy) and secondly the transection or ligation of the efferent ducts of these glands in either sex (vasectomy, salpingectomy). The third method which we especially advocate as a substitute for castration and whose practicability and efficiency should be investigated is that of Roentgenization of the testes or the ovaries. All of these methods are or can be made to be efficient methods for the destruction of procreative power and thus far at least satisfy the sociological requirements. Consequently our consideration of them may be directed to their physiological conditions and consequences.

The writer desires to make the abandonment of castration and the development and substitution of other less objectionable methods of sterilization the chief object of the present discussion. If it can be shown that the sexual glands are organs of internal secretion having an important relation to the processes of growth and metabolism and to the nonsexual organs or functions, this fact alone would be sufficient to raise a physiological doubt of the advisability of castration at any period of the individual's existence. If in addition it can be shown that other physiologically less destructive methods successfully remove the power of procreation then it becomes still more advisable to dispense with castration. The writer believes that in the present state of scientific investigation both of the preceding questions admit of answers sufficiently positive to appeal to the physiological sense of those competent to judge. As a preliminary critical observation it should be noted that investigation in the field of gland physiology has not yet by any means reached its culmination; that the subject-matter is difficult and involved and has been pursued perhaps only two decades from a modern standpoint. The more critical the analysis of the available data the more

keenly is felt the need of further observation. In view of these conditions the ready haste and positive zeal of the majority of those who deal with the subject of sterilization in a practical way commends itself very poorly to scientific judgment.

The first physiological fact having a cogent bearing on our proposition as above stated is that the male sexual glands have a double function which is both generative and secretory. As sexual generative glands they produce and extrude the male germinal elements, viz., the spermatozoa. This fact is so well known that only the second function, that of internal secretion, could possibly be called in question. What then is the evidence for the internal secretion of the testes and of what significance is this function for the remainder of the organism?*

The long line of castration experiments made on mammalian subjects including the human body might here be cited. We shall pass over most of this fact-material briefly, not because of its lack of significance, but because it is well known and we are now in a position to offer more direct evidence on the same subject. When the castration experiment is performed on the *immature* mammalian body there is unmistakable evidence of its influence upon other than the sexual organs. The evidence for this statement is so abundant in the literature that we need not repeat it here, but the following very recent data obtained on human adults who had been early castrated may be cited to show the influence of castration upon other glands of internal secretion in man. Tandler and Grosz found the thyroid glands noticeably small in these castrates. The weight of the alcoholic specimen was 13 gm. compared with 45.8 gm. for that of a normal adult. In the Skopts (a Russian sect practising castration) whom they examined they never found an enlarged thyroid. The thymus gland in early human castration persists abnormally long. With reference to the pituitary, the fossa hypophyseos was found notably broad, long, and deep. Itaka Kon found the hypophyses of castrates on an average 1 to 5 gm. heavier and in measurements several millimeters larger than normal. The earlier in the individual's life the castration is performed the more marked are the results, whereas late castration brings about only minor somatic changes so far as morphological characters are concerned. Among the easily observable results are obesity in many cases, early grayness of the hair, falling out of the beard hairs, according to some reports involutionary processes in the genitals, changes of the skin like those observed in early castrates, gradual loss of the power of erection and of the libido sexualis. More observation has been given to the effects of castration upon women. Without going into detail we may note that the resulting physiological disturbance is apparently more marked than in men.

To the physiological mind these secondary effects at once raise the question whether the non-sexual capacities of the reproductive glands, which capacities have now been incidentally and unintentionally removed, are not so necessary or so advantageous to the organism that they should not be ignorantly and unwittingly removed. If it be replied that castration of the adult has no such remote effects, then we ask where is the evidence. How much investigative study has been devoted to the determination of the physiological condition of castrated individuals? Our criticism is that we have made very many castrations based on our ignorant assumption of physiological knowledge but we have concerned ourselves little or not at all with the scientific study of these subjects after the operation. We cannot dignify with the term physiological observation or with the term scientific the popular physical or ocular and casual examination whereby the occasional fatness and the lethargy of the castrated subjects have come to be regarded popularly as very desirable and very satisfactory results. The whole trend of modern physiological investigation of the sexual glands is to regard them as having a very important relation to the processes of metabolism of the body generally. Lubarsch terms them "the regulators of metabolism." As the castration of women has frequently been performed as a therapeutic measure in osteomalacia there have been many observations on the subsequent conditions of nutrition. Various observers found an alteration in the lime and phosphorous metabolism which has, however, been doubted by others. Some have held that these changes exist at first but are of only temporary duration. The influence of the sexual glands upon the mineral metabolism is well shown by the fact that the administration of ovarian or testicular substance will restore the metabolic equilibrium. According to Loewy and Richter the oxygen consumption sinks 20 per cent. upon the removal of the ovaries, whereby fat is notably spared. After the administration of animal ovarial substance normal relations are restored or the oxygen consumption even exceeds the normal. According to Luethje, Neumann, and Vas the nitrogen balance is not changed by castration. Alterations in the blood have been found by Adler who correlates the lengthened coagulation time which he found in both man and animals after removal of the ovaries, with the calcium content of the blood.

These considerations indicate the possible nature of the effects which may follow castration of the adult. They indicate that the scientific study of the subjects of this operation should proceed along the lines of their metabolism. The meagerness and the uncertainty of the results of this nature thus far obtained do not show that this investigation is unnecessary. They serve to give emphasis to the proposition that before we settle upon castration as a scientifically commendable and legally justifiable procedure we determine by exact and thorough investigation what the physiological conditions and results are. This implies that the subjects to be operated be studied for a period both before and after the operation and those who are familiar with the requirements of a metabolism investigation know that this is a laborious undertaking if it is to be pursued to an established conclusion.

We may now turn to the direct evidence for the power of internal secretion by the sexual glands. We shall have to recall the distinction between the primary and the secondary sexual characters, *i.e.*, the distinction between sexual and somatic organs. As above stated castration experiments upon the immature body have shown the influence of the sexual glands upon distantly situated organs. For the concrete character of these changes we refer the

*The literature cited or collated in the present discussion as well as additional data and references can be found in the following publications:

Tandler, J., und Grosz, S.: "Die biologischen Grundlagen der sekundären Geschlechtscharaktere," Berlin, 1913.

Biedl, A.: "Innere Sekretion," 2te Auflage, 2 Teil, Berlin, 1913.

Falta, W.: "Die Erkrankungen der Blutdrüsen," Berlin, 1913.

reader to the literature, including that which deals with the subject of internal secretion. This influence at a distance from the anatomical location of the primary disturbance was formerly ascribed to direct nervous action. The abandonment of this explanation was due to the discovery of a new method whereby one organ, especially a gland, may act upon other organs, *i.e.*, by means of secreted and chemically and physiologically characterized substances called hormones which are poured into the blood stream. The existence and action and in some cases the nature (*e.g.* adrenalin) of hormones is now too well established to be called in question. The effect of castration upon the secondary sexual characters of man and mammals is strong evidence of the production of hormones by the sexual glands and thus of an additional function to that of producing the germinal cells, viz., the spermatozoa. However, this evidence may be established beyond all possibility of doubt by other evidence that is both anatomical and physiological. This additional evidence we shall describe not so much because of its logical necessity, as for the light it will throw upon the question of the advisability or the necessity of castration especially in view of the possibility of other less drastic procedures.

Histologists have long recognized in the sexual glands at least two classes of cells. One of these may be called, after Tandler and Grosz, the *generative* cells which have the function of producing the gametes, *i.e.* the spermatozoa and the ova. The other class has nothing to do with this production and impresses the observer as if it were merely supporting tissue. These latter are known as the interstitial cells of Leydig by whom they were discovered in mammals in 1850 and they were first observed by Koelliker in human testes in 1852. Of course nervous, muscular, and connective tissues are also present. Into the descriptive histology of these cells, their seasonal and species variations, and the detailed history of our gradually developing idea of their function we cannot enter here. Suffice it to say that in 1902 Mosselmann and Rubay first expressed the opinion that the interstitial cells influence the development of the secondary sexual characters. During a period of years thereafter Ancel and Bouin as a result of extensive morphological and experimental investigation developed the important proposition that the influence of the testes upon the organism in general is due to these interstitial cells. Finally we have a series of investigations which trace the interstitial cells as a gland of internal secretion affecting not only the secondary sexual characters *but also the other glands of internal secretion.* In view of the now well known importance of the integrity of the system of the glands of internal secretion for the most varied physiological functions, other than sexual, this relation of the interstitial cells should be critically weighed in passing judgment on the effect of castration particularly if interference with this relation is avoidable. It may here be noted that in the female also the analogous interstitial cells have been found among the tissues of the ovary.

Seeing that there is the greatest unanimity among histologists regarding the morphology of the interstitial cells let us turn to the experimental testing of their function. It has been found that in the Roentgenization of the sexual glands we have a means of eliminating the generative function while preserving the interstitial cells both morphologically and in their power of internal secretion. This is a most important proposition and requires a description of the data on which it is based. Albers-Schoenberg in 1903 observed that after intense Roentgenization of rabbits and guinea-pigs the potentia generandi was lost but the potentia coeundi remained. Histological examination by Frieben of the testes of these same animals showed that the epithelium of the seminiferous tubules had disappeared and that there was a complete want of spermatogenesis. Bergonie and Tribondeau in 1905-6 confirmed these findings and developed the additional and significant fact that the interstitial cells remain intact. In 1906 Villemin expressed the opinion that only the interstitial cells of the testes possess the function of internal secretion. Further details of the comportment of these cells under Roentgenization we shall have to omit here but the subsequent and very definite experiments of Tandler and Grosz should be described for their bearing upon the question of internal secretion of interstitial cells. In 1908 they reported that if roebucks are castrated at the time when they are bearing antlers they will cast these within the next few weeks and will then develop in their place a distorted but now perennial antler called a peruke-antler. This process offers then a good means of determining the influence of the sexual glands upon a distant secondary sexual character. Then proceeding from the established fact that Roentgenization destroys the generative portion of the gland while saving the interstitial part the experiment was made of treating the testes of three roebucks with the Roentgen rays. After several months a microscopical examination was made of one of the testicles of each animal. This showed the complete destruction of the epithelium of the seminiferous canals and the consequent loss of spermatogenesis, but the interstitial cells were normal. Comparison was also made with normal testes. How now did these Roentgenized animals comport themselves with reference to the development and casting of antlers? The result was no observable distinction in this secondary sexual process between the Roentgenized and the normal roebucks. The effects of castration then were due to the loss of the interstitial secretory cells, for the generative cells were destroyed by both castration and Roentgenization. (See Tandler and Gresz, *loc. cit.*, pp. 99-103.)

The secretory function of the interstitial cells is thus experimentally demonstrated and with this result it becomes clear that the operation of castration makes deeper inroads upon the physiological integrity of the organism than is either necessary or intentional. Furthermore the unanimity of many different experimenters to the effect that by Roentgenization it is easily possible to eliminate the power of procreation without destroying the interstitial cells certainly suggests that it would be far more scientific as well as physiologically effective to substitute the Roentgen ray treatment for castration. Those who are familiar with the logic of physiological experiments will at once recognize the validity of the previously described experiments for the human subject but we nevertheless make the following quotation from Tandler and Grosz, *loc. cit.*, page 107: "Here belongs above all the well-known fact, which we ourselves have been able to establish free from objection, that persons who must expose themselves to the Roentgen rays professionally, become sterile, *i.e.* they lose the functional capacity of the generative part of the sexual glands, without thus suffering any damage to other somatic or

psychical sex characters. The sterilization of women for various therapeutic indications has often been undertaken recently, but without the elimination phenomena of castration having appeared."

We may now turn briefly to another procedure used for the sterilization of the male, that of vasectomy. Here also we meet with the conclusive result experimentally established that this procedure results in the loss of spermatogenesis with the retention of the integrity of the Sertoli cells and of the interstitial cells. Bouin and Ansel showed by numerous experiments on guinea-pigs, rabbits, and dogs that after ligation of the vas deferens spermatogenesis disappears within a period of eight to twelve months thereafter. They also call attention to the resemblance of such experimental testes to those which are cryptorchic. Animals thus treated retain the sexual instinct and do not change their secondary sexual characters. Tandler and Grosz have confirmed these results by experiments upon roebucks which are equally conclusive as those previously described on Roentgenization. They thus lead to the same conclusion that the interstitial cells have an internal secretory function which would be removed by castration. To avoid a possible wrong inference we again quote from Tandler and Grosz, *loc. cit.*, page 107: "The transection of the tube cannot be compared in its action with vasectomy, because by the former operation the ovary remains fully intact in its function. This is taught with unanimity by the animal experiments of Sellheim, Foges, etc., and by therapeutic sterilizations on the human female."

While this paper was not written primarily to advocate vasectomy we may note in passing the frequently made criticism that a junction might be regenerated by the vas deferens with the implication that the procedure would thus be nullified. This particular objection to vasectomy has probably little or no legitimate force as this is a matter of surgical efficiency. On the subject of such regeneration there seem to be no experimental data available. The logically essential and practically important question is not whether this regeneration of the vas deferens can occur, but whether the *power of spermatogenesis*, having once been removed by a successful vasectomy, can be reproduced. The regeneration of such pathologically destroyed tissue is a very unfamiliar biological phenomenon. Tandler and Grosz assert (*loc. cit.*, page 106): "Vasectomy doubtless brings about a permanent destruction of the generative part of the germinal gland."

We may summarize our conclusions as follows:

1. The sexual glands are not only reproductive in function but they are also organs of internal secretion which have an important relation to the processes of growth and metabolism and to the non-sexual organs and functions. The distinction between these two functions has an anatomical basis in the local and histological differences between the generative and the interstitial cells of these glands as distinguished by Tandler and Grosz. The functional distinction between these two classes of cells is borne out by an extensive series of physiological experiments as described in numerous and recent investigations.

2. By the procedure of castration the subject is deprived of the internal secretory functions of the sexual glands whereas the primary intention is to deprive him only of the power of procreation. The extent of the derangement of internal metabolic functions thus induced has never been studied except superficially. The procedure has been assumed to be physiologically harmless and commendable. It should be further studied from the standpoint of its metabolic effects before it is adopted on a wholesale or legal scale, as is now contemplated by many, for the sterilization of the mentally defective. The tendency of increasing knowledge is to show that a normal mentality and a normal nervous system cannot be developed nor even maintained without the adequate functioning of the system of glands of internal secretion.

3. Since castration is an operation performed in ignorance of its physiological significance and rests more on customary than on scientific grounds for its justification it has no claims to preference over other methods which could be tentatively tried in its stead. I therefore propose as a method for investigation the Roentgen ray treatment of the testes and ovaries of properly selected cases under skilled hands, and, may it be emphasized, under adequate physiological and metabolic control of the effects produced. From the data previously cited in this paper the Roentgen ray treatment appears to be an effective method of sterilization, it does no violence to the anatomical integrity of the body, and it appears to cause the smallest possible amount of physiological destruction. The argument of the present paper is made to induce the temporary abandonment of castration and merely to place on trial the apparently excellent claims of the Roentgen ray sterilization.

A PLEA FOR THE MORE RATIONAL USE OF VACCINES.*

By S. R. BLATTEIS, M.D.,

BROOKLYN, N. Y.

PATHOLOGIST AND ASSOCIATE VISITING PHYSICIAN TO THE JEWISH HOSPITAL OF BROOKLYN; ASSISTANT TO THE CHAIR OF MEDICINE, UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE.

To present at this late day to a body of medical men a paper on vaccines or bacterins seems like carrying coal to Newcastle. Yet there is scarcely another branch of medicine about which the general practitioner's knowledge is so indefinite. This statement, however, is not made in any disparaging sense. Most physicians have gained their knowledge on this subject from current literature or from a limited experience. They have not had a systematic course of instruction on vaccines such as is given in other subjects in a medical curriculum. The existing diversity of views can, therefore, be partly accounted for in this way. The writers' views on this subject are the result of an experience of over five years of intimate and constant use of vaccines in all branches of medicine, and mostly in the wards of the Jewish Hospital.

That any new method of treatment should be grasped with such avidity as this has been is little wonder, for on one side are the hundreds of diseases to which flesh is heir, and on the other but a handful of specifics with which to combat them. Attempts to equalize the contending forces in this unequal struggle against the infectious diseases constitute the main object of the use of vaccines or bacterins.

A brief elemental consideration of the terminology and of the theory of the use of vaccines may

*Read before the East New York Medical Society, December, 1913.

not be superfluous, owing to the confusion in the minds of many men on this part of the subject. Vaccines are suspensions or emulsions of bacteria in normal saline. A vaccine is not a serum. It seems necessary to emphasize this, as the distinction is not clear to many, though it presents not the slightest difficulty. A serum is at all times and under all circumstances the fluid portion of blood after the formation of a clot. The therapeutic differences between a serum and a vaccine are as distinct as their biological ones.

A vaccine or bacterin may contain one organism only, in which case it is named after that organism, as a staphylococcus vaccine, a streptococcus vaccine, etc., or it may contain two or more different organisms and constitute a mixed vaccine. It may, furthermore, be made up of one organism only, but of many types or strains of that organism, and be known as a polyvalent vaccine. The same term is applied to one organism obtained from a variety of lesions. And, depending upon whether it contains a staphylococcus or a streptococcus, the vaccine is a polyvalent staphylococcus or a polyvalent streptococcus vaccine. A vaccine or bacterin made from the patient's own lesion and reintroduced into that patient is an autogenous vaccine. This is in contradistinction to an emulsion of bacteria derived from some source outside of the patient and which is known as a stock vaccine. The autogenous vaccine cannot be polyvalent, for in this case one is dealing only with one strain of an organism, while a stock vaccine may be univalent or polyvalent. Autogenous vaccines like stock vaccines may be mixed if the disease, as in rare cases, is a mixed infection. When a vaccine is used in advance of a disease, its use is termed protective or prophylactic; when used in the course of a disease its use is termed curative or therapeutic.

What is the condition of the bacteria making up the vaccine or bacterin? In the vaccines commonly employed the bacteria are dead; they are killed usually by exposure to heat, or, in rare instances, by chemicals. However, dead bacteria are not the only kind that may be employed. Living or viable bacteria have been used very frequently. When live bacteria make up a vaccine some process is employed by which their virulence is diminished or attenuated, and though they remain viable they are no longer pathogenic.

In the laboratory of the Jewish Hospital we early became impressed with the fact that to produce the greatest specific reaction to an organism that organism must be as nearly as possible in the living or viable state, and yet not pathogenic. We found that by exposing bacteria to just below their maximum temperature for several days in succession would so change them that, where heretofore a given dose proved fatal to animals, the same dose, after treating the bacteria as described, would be entirely harmless. Numerous injections of this kind of vaccine were made, and in no instance did a local infection result. In fact, it was not generally known that this method of treatment was in vogue. Constitutionally, the cases so treated at no time showed any change in the clinical picture for the worse that could not be readily accounted for by the disease itself.

Another method for attenuating bacteria is the one described by Besredka in his use, at first of a typhoid vaccine, and later of a number of other vaccines. He found that when he mixed with the bacteria heated beef serum or rabbit serum, the bacteria would remain viable, but a previously lethal dose would not now cause death of the animal. He found the same thing to hold true when, after adding his serum, he centrifuged and washed the bacteria in saline. This change in the pathogenic properties of the organism he termed a sensitizing process, and the vaccine prepared in this way a sensitized virus-vaccine. He now uses the specific antiserum to sensitize his bacteria—*i.e.*, if he wishes to sensitize typhoid bacteria he uses the serum of a typhoid case, etc.

No presentation of the subject of vaccine or bacterin therapy is complete without some consideration of the subject of immunity. There are a few elemental principles relating to this subject which have stood the test of time and experience. Immunity is resistance to disease, or, more exactly, it represents the total of all the elements which constitute resistance to infection. The varieties into which it may be classified are self-evident: Natural immunity is that type usually inherited; the acquired type may result either from an attack of an infectious disease, as typhoid fever, scarlet fever, etc., or may be produced by artificial means, as with specific viruses, specific sera, and specific vaccines or bacterins. When the body does not take part in the manufacture of any immune elements, but has these elements already contained in the substance injected, as the antitoxin in the various sera, then, as we know, this represents the passive form of acquired immunity. When, however, the substances injected do not contain any ready made immune bodies, but depend for their production on the stimulating properties of the inoculated material, then this is classified as active acquired immunity. Those substances which stimulate the production of immune bodies are known as antigens, and vaccines or bacterins are the best example of an antigen. Those substances formed in the body as the result of the presence of an antigen are known as antibodies or immune bodies, and include most prominently antitoxins which neutralize the poisons of bacteria, bacteriolysins which destroy the bacteria themselves, and opsonins whose presence in the blood facilitates phagocytosis.

A word on the opsonic index. It is common knowledge that when leucocytes are washed free of all serum and mixed with a suspension of bacteria, alive or dead, and incubated, that few or none of the bacteria will be taken up by these leucocytes, but this same mixture of bacteria and washed leucocytes, with the addition of serum, will show after incubation that phagocytosis is active. That the serum contains something that facilitates phagocytosis is, therefore, the simplest of laboratory demonstrations. If now the number of bacteria in a certain number of leucocytes is counted, and an average determined of the number of bacteria per leucocyte, that average is known as the phagocytic index. This phagocytic index of the patient divided by the average phagocytic index of a number of normal persons, is known as the opsonic index.

Though the steps in the determination of the opsonic index are plain, yet the procedure necessitates such a complexity of detail that it becomes impracticable as a routine measure. Not only because of its impracticability, but also because of the variation in the results obtained by the very

best authorities, has the determination of the opsonic index been abandoned as a routine. This does not in the least detract from the brilliancy of the observations of Wright and his associates, nor does it imply that in skilled hands this method would not in certain intractable cases of chronic localized infection give the proper clue to the dose and to the frequency of injections of vaccine.

Following the use of bacterins, there are certain "phases of reaction" about which there has been the greatest confusion in the minds of the profession in general; this misconception at one time threatened the adoption of vaccine therapy; as it is, it has done immeasurable harm. The phases of reaction are termed negative and positive. By the negative phase Wright means that period immediately following the injection of a vaccine and lasting about twenty-four hours, during which the opsonic index, measured by the degree of phagocytosis, as previously explained, is lessened. This is succeeded by the positive phase or a heightening of the opsonic index above the normal. Clinically, the negative phase is interpreted to mean that feeling experienced by the inoculated individual, of malaise, anorexia, headache, slight elevation of temperature, and an occasional temporary aggravation of the local symptoms. Wright gave this phase a significance which subsequent experience did not confirm. He taught that during this period the body resistance to the particular infection was diminished and the individual was made more susceptible to the disease. This he said about 1898-1900, and caused the temporary abandoning of prophylactic inoculation against typhoid fever, which was then being performed in the English army engaged in the Boer War, where typhoid fever was prevalent. The reasoning for that step was as follows: If after an injection of typhoid vaccine a person became more susceptible, therefore, while it may be done with impunity when the disease is not prevalent, it does become dangerous whenever the disease is raging.

To prove that this is not so I can speak from a personal experience, which, on account of circumstances, has been exceptionally rich, and includes a record of over 1,000 antityphoid inoculations of three injections each, performed since January 15, 1913. Many of these were given under conditions ideal for the development of secondary cases, conditions complying with all the requirements of Wright's negative phase, and yet not in any one case did typhoid fever develop after the process of immunization had been completed. On the other hand, where no inoculation was performed, instances of secondary infection were not at all uncommon. I regret very much that I have not time to dwell more at length upon this branch of the subject, and describe in detail some of the cases observed, but I must mention a few: (1) Mother and infant visiting relatives in the city; four days after arrival infant develops what subsequently became typhoid, contracted from milk bought at a neighboring farm at home in which a case of typhoid had occurred. The number exposed to the infection was five, of which the father and two sons of the family being visited consented to be inoculated. The mother of the sick infant and the wife eluded all attempts. Consequences: Those inoculated escaped; the others were both taken to a hospital, where they ran a severe course of typhoid fever. A further illustration: A child took sick with indefinite symptoms that proved to be typhoid fever. The mother and father were inoculated; the nurse refused; mother and father remained well; the nurse contracted typhoid fever. One more instance: A young man had typhoid fever; a brother and sister not inoculated contracted the disease; the mother and the other sister inoculated remained well. And so I could go on.

It is of importance to feel certain that persons about to receive prophylactic injections of typhoid vaccines are not in the prodromal period of the disease, for the result of an injection at this time is to bring about, somewhat more abrutly, the period of invasion. Experience teaches that one prophylactic injection neither produces any degree of immunity, nor changes in any way the usual clinical course of the disease. Individuals in the incubation period of the disease will not have the disease aborted, though the general experience testifies to the clinical fact that the course of a case of typhoid fever that has received two or three prophylactic injections is milder and more free from complications than when no injection has been given. That one or more prophylactic injections of typhoid vaccine can produce typhoid fever is from every point of view preposterous. We furthermore know that the hyperdermic injection of avirulent or sensitized living typhoid bacilli does not reproduce the disease. The following are the conclusions at which the writer has arrived with regard to the use of typhoid vaccine: For prophylaxis in typhoid fever its use is specific and it affords absolute protection. In the presence of direct exposure no contraindication to its use exists. As a routine procedure in individuals not exposed, heart cases, and proved cases of pulmonary tuberculosis should be passed; the menstrual period should also be avoided. The vaccine does not produce abortion at any period of pregnancy. The reaction experienced rarely incapacities, and is seldom severe. Fear of the after-effects need never deter a physician nor be accepted by him as an excuse. When one considers that the statistics of hundreds of thousands of cases prove that antityphoid inoculation is more efficacious than vaccination against smallpox, it becomes needless to urge the present-day practitioner of medicine that while it may not be practicable for him to prevent primary infection with the typhoid bacillus, it is absolutely within his power to prevent the occurrence of secondary cases. This will immediately reduce the number of cases in one year by thousands, and save hundreds of lives.

All this is incidental and used in the discussion of the negative phase after vaccine injection. Before leaving this part of the subject, I emphatically state that I hold the negative phase to mean simply the reaction of the body to the stimulus of the organism or its metabolic products injected; it differs only in the degree of severity from the reaction following the inoculation of vaccine virus; it in each instance produces a mild, often imperceptible, attack of that particular infection; it no more represents a stage of lessened resistance to infection by that specific organism, than vaccinia represents a susceptibility to smallpox. The positive phase is represented clinically by an amelioration of symptoms, and corresponds theoretically to the production of a sufficient amount of specific antibodies to effect a neutralization, usually only in part, of the disease-producing agent, whether it be a toxin, a living bacterium, etc. Theoretically, the produc-

tion of immunity with vaccines or bacterins is smooth sailing. But a number of factors arise which produce trouble. It must be primarily borne in mind that the process of immunity is a delicate one, and very likely, biologically and chemically, a complex one. That we have not yet solved all the problems entering into the question, there can be no doubt; for it is scarcely more than a decade since this subject began to engage the close attention of research workers. But this much can be laid down as a law, upon whose recognition depends the accurate conception of this subject, namely: the antibody formed as the result of the presence of an antigen, is always specific for that antigen; or, the immune bodies produced by the injection of bacteria are specific for these organisms. In other words, the injection of a streptococcus vaccine produces immune bodies that are of use in neutralizing the toxins of streptococci only, and no other; these immune bodies will not neutralize the toxins of staphylococci, of colon bacilli, or of any other; and, conversely, staphylococci or colon bacilli, when injected, will not produce immune bodies that are of any use whatever in the neutralization of the toxins produced by streptococci. Furthermore, it must be borne in mind that the different types or strains of one organism produce antibodies that are specific, not for the entire species, but for that type only: for instance, the immune bodies of a streptococcus hemolyticus do not act on a nonhemolytic streptococcus. That nearly all organisms have different types peculiar to particular species has been proved beyond doubt. That the immune bodies are specific for each peculiar type or strain of an organism, has been conclusively proved.

The following facts should be emphasized: Autogenous vaccines or bacterins are the only vaccines to be employed in order to comply with the scientific theoretical conception and experimental evidence. Stock vaccines to be of any use whatever must be of that organism which has the fewest number of strains, should be polyvalent, and should be used only for chronic or subacute localized infections. Mixed vaccines are to be used only when a mixed infection has been bacteriologically proved to be present, or tangible evidence is at hand to lead one to suspect its presence. Only in rare instances, according to undisputed scientific evidence, are mixed vaccines to be used. Not only is the indiscriminate use of mixed vaccines unscientific and useless, but harm results from their use, for the reason that, as physiology teaches, tissue cells have a limited capacity to react to stimuli, chemical, electrical, or biological. In bacterial infections the stimulus is the specific organism or its toxin; tissue cells react to this stimulus by producing specific antibodies; the larger the amount of specific antibodies the cell is made to produce by a vaccine the greater is its therapeutic efficiency. If, however, instead of reacting to the specific organism alone, the cell is called upon to divide its reacting capacity in the production of antibodies to two, four, six, or even more varieties of organisms, then the ability of the cell to manufacture the specific antibody is reduced, at least, in direct proportion to the number of nonspecific organisms contained in the vaccine.

If the principles upon which the use of vaccines depends are to be observed, then it is manifestly illogical and, to say the least, bad therapeutics to employ this therapeutic agent in a manner diametrically opposed to its basic principles.

350 New York Avenue.

NOTES ON THE USE OF RADIUM IN TREATMENT OF DISEASES OF THE EAR.

By W. SOHIER BRYANT, A.M., M.D., F.A.C.S.,

NEW YORK.

The use of radium in the treatment of diseases of the ear offers the means to fulfil efficiently two urgent requirements in otology: first, the stimulation of cell-growth; and second, the destruction of cells. In the majority of chronic otological cases, the desiderata are the proliferation of normal tissue cells and the destruction of new-formed cellular and cicatricial tissues. Radioactive therapy presents these two desirable and diverse modes of action, which can be used either singly or together. Often we wish to use both of these processes at the same time in the same ear.

In hypertrophic and cicatricial states the destructive action of radium is desired; in atrophic states the stimulating effect is desired. The destructive action of the radium is sought particularly in cicatricial states of the middle ear or in degenerations of the auditory nerve and labyrinthine mechanism. In atrophic and degenerative states, atrophic middle ear catarrh, otosclerosis and auditory neuritis and labyrinthitis, the action desired is stimulation of the growth of the remaining normal cells as well as the destruction of the pathological tissues.

There are four processes apparent in the action of radium in ear diseases and they are of varying importance: (1) the presence of the radium capsule in the auditory canal acts as an irritant, as any foreign body acts; (2) the heat evolved by the radium has a warming effect on the meatus; (3) the electrical activity of the radium ionizes the surrounding matter; and (4) the radiation of the radium produces diverse effects, depending upon the individual and upon the dosage. The rays of radioactive substances are of three kinds. The shallow, penetrating, slow α rays act only as a superficial destructive agent. Their action is not desirable in the treatment of ear disease, and therefore they should be eliminated by filters. Another variety of rays are the rapid γ rays. These rays penetrate deeply and break up into β rays. The various intermediate rays between the α rays and the γ rays are the β rays. These β rays are now considered the most important therapeutically. From an otological point of view also these rays are most significant, for to them are attributed the two apparently antagonistic activities of stimulation of desirable tissue on one hand and destruction of undesirable tissue on the other hand. In my treatment I use mesothorium bromide because it is the richest in β rays.

In the use of radium for the treatment of aural diseases, as in the use of radium for the treatment of diseases of any kind, precise care should be exerted in every possible direction, so that there may be no overuse or no misuse. The reaction of the individual must be carefully watched and determined; the dosage of the application must be nicely gauged; and the equation of the applicator used must be carefully studied. Because of the comparative newness of the treatment there is practically no literature on the use of radium in ear diseases. I consider that too much care cannot be used in determining the susceptibility of the individual to the action of radium. There is, of course, a wide range of reaction in individuals and there is little known of the indication of the relative susceptibility of an individual; the amount of reaction to the radium

can as yet be determined only by careful experiment. We can, therefore, see the importance of the utmost caution in the employment of radium lest we do more harm than good. Overuse shows in deterioration of the hearing. In the use of radium the first effort should be to avoid damaging anything. Before I applied the capsule I now use, I exposed my skin to it without harmful results for a period much longer than I have ever used it in the ear.

The technique of the radiation depends upon the kind of radioactive substance used, its concentration, upon the amount used, its area, the distance of application, the filterage, and the length of exposure. The applications should always commence at a minimum and be gradually increased, the time and length of an exposure being governed, of course, by the result of the previous exposure. The intervals between the applications should also be carefully graded. The greatest difficulty in the appropriate dosage of radium is the fact that the effect may be long delayed and may not appear for months after the application. Every applicator should be considered an entirely new instrument. Each applicator has its own equation; it must be studied separately and its effect measured. Other applicators, even though containing the same amount of radioactive substance, are only a very general guide to an applicator, for the minute individual variations make a great deal of difference in the results. The applicator I use is a glass tube containing 5 milligrams of mesothorium bromide wrapped in thin tinfoil. The applications were made in the auditory canal.

The limitations or contraindications for the use of radium have not as yet been definitely established. Apparently the only conditions in which there is no indication for its use are those in which the functions of the ear are normal and those in which the labyrinth has been entirely destroyed, and all function annihilated; in other words, when there is nothing to use radiation for and where there is nothing to use radiation on. Local radiation of radioactive substances does not appear to have much influence on the causal factors of ear disease, but its action offers a specific for the residual effects of ear disease; that is, radioactive therapy seems to be not so effective in the treatment of causes, as it is in the treatment of the effects of the causes. The causal factor of ear disease should be eliminated before recourse is had to radiation. In order, therefore, to obtain the best and permanent results, it is usually indicated that other treatment be used and that radium be considered an adjunct to this treatment. The practical indications for the use of radiation are all forms of functional derangement of the ear when the causal factors have been eliminated. The use of radium in ear disease is indicated and is most effective in static and terminal conditions. Besides these advantages, it has another in the fact that it renders certain cases amenable to treatment that would not yield to other means.

SUMMARY OF CASES

20 CASES—40 EARS.

Otosclerosis	9 ears
Atrophic middle ear catarrh	12 "
Effects of middle ear suppurations	13 "
Non-suppurative labyrinthitis	2 "
Hypertrophic middle ear catarrh	4 "

RESULTS

Hearing decreased in 1 ear	(Non-suppurative labyrinthitis.)
Hearing unchanged in 6 ears	(2 atrophic middle ear catarrh.) (4 effects of middle ear suppuration
Hearing improved in 33 ears	
Much improved in 14 ears	(6 atrophic middle ear catarrh.) (2 hypertrophic middle ear catarrh.) (1 non-suppurative labyriothitis.) (3 otosclerosis.) (2 effects of chronic middle ear suppuration.)
Restored to normal in 6 ears	(2 hypertrophic middle ear catarrh.) (4 atrophic middle ear catarrh.)

†Hears shout with ear trumpet.

‡Hears voice without ear trumpet.

To give a general idea of my results of the treatment with a radioactive substance, I submit the data on a series of twenty consecutive cases. The cases are not selected on any basis other than chronicity. The cases were all seen in private practice, and all had been under my observation for a number of years before radiation was used.

The hearing was measured by a 60-inch watch and a 2,400-inch Politzer acoumeter.

PELLAGRA

By J. R. LOWERY, M.D.,

RALEIGH, N. C.

HAVING seen and treated a number of cases of pellagra during the past five years, I have reached the conclusion that the disease is due to the absorption of poisons from the intestinal tract. We have had pellagra in the South for a number of years, but the cases were so sporadic the malady for some time was not identified. It has been gradually increasing, however, for the past few years, which I think is due to the fact that we eat different food prepared in a different way from that of a half century ago.

The bread we ate then was made of flour from the old burr mill, containing much bran, which, while it was indigestible, yet passed into the intestines and acted as a blotter to absorb and carry away the poisonous products from the sewer of the body. White bread, made of flour from the modern roller mill, is practically all digested, and so leaves no residue as a stimulus to intestinal action. The vegetables and meats we ate then came fresh from the farm, but with the coming of the railroad we began to be supplied with food that had been shipped many miles and undergone decomposition. It will be remembered that the probable cause of the disease was at first attributed to the use of decayed corn, or corn in some process of decay. Bread made from unsound corn meal may contribute, or even be the main factor, in producing these poisons, but bread made from unsound wheat flour may produce these poisons also, and I think really does produce more poisons, than corn meal; especially bread made from flour of wheat that has been stored for many weeks or months in large elevators, containing many thousands of bushels, where it may undergo deleterious changes. Dr. Driscol and Dr. Monroe, of Georgia, report several cases of pellagra, the symptoms of which disappeared in a few weeks after the patients had been put upon a diet of bread made from corn meal, with half its volume of bran. They think there is some vitamine in the bran that produces the results. I think, however, they are produced because the bran does not digest, but passes through the intestines, absorbing and carrying off the poisons from the intestinal tract. Yet, these poisons alone rarely cause pellagra; there must be something that lowers the tissues. A person that is healthy is able to throw off and resist the invasions of these toxins.

The most common causes of lowered resistance power are childbirth, tuberculosis, malaria, and poor hygienic surroundings. Eighty-one per cent. of all my cases were females. Of these 77 per cent had borne a child within one year prior to the first symptoms. And I think, therefore, that childbearing, which lowers the resistance of the body, and the sedentary habits of women, which produce constipation and cause thereby the poisons to be retained in the intestines longer, resulting in greater absorption, are the reasons why we find pellagra more common in the female.

The Thompson-McFaden Pellagra Commission found that the rate of prevalence among males drops between the ages of nineteen and forty-five. I think this is due to the fact that man has greater resistance power between these ages. This same report also shows an increased prevalence of the disease among females betwen the ages of nineteen and forty-five. This, I think, is because that is the childbearing period of women, especially among the poorer classes with their insufficient food and bad hygienic surroundings, rendering them unable to resist the invasion of intestinal fermentation, under the extra strain put upon them by pregnancy and childbirth. I have examined the urine of the majority of my cases and find nothing definite. In most of the cases, especially those of a chronic nature, the stomach analyses show a diminished amount of hydrochloric acid and ferments, but this is due to the inflammation of the mucous membrane of the gastrointestinal tract. In some cases I found an excess of acid, but these were cases in the incipient stages. Dr. Pendleton examined the blood of a number of these cases and discovered nothing definite. I have found in all cases a great increase in the number of bacteria of all kind in the feces with much white mucus.

Sambon thinks that the spread of pellagra is due to a gnat that lives near streams, as he found more cases among field laborers that lived near water courses. For this reason, in his opinion, women had it more often than men as they went to the streams after water and looked after the cows that grazed near streams. But in this country we have more cases in cotton mill districts remote from rivers, and so, I think, the trouble is rather due to their getting wages inadequate to the supply of good food, together with long hours of work that lower their resistance power, leaving them pale and anemic.

I know of one cotton mill town of 2,000 people situated on a river, the people living on both sides in houses situated near the banks, and there has been but one case of pellagra in this town, and this patient lived one mile from the stream and town. I attribute this to the fact that this town was situated out in the country, and the operatives ate food brought in every day from the surrounding farms, which really is the best food that can be found anywhere. Moreover, as this settlement was in the country, where there were no attractions to go to at night, there was nothing to prevent the operatives from getting the proper amount of rest and sleep.

One of my pellagra patients was a very wealthy man; he had always eaten good food, and had had no previous disease to lower his resistance, but he had one of the most stubborn cases of constipation, going sometimes for a week without an evacuation of the bowels. Evidently it was the absorption of the poisons from the intestines that induced the disease in this case.

The symptoms of pellagra are many, but the most important in making a diagnosis are swimming of the head, shortness of memory, sore mouth, digestive disturbances, nervousness, sore rectum, burning of the feet and legs.

Vertigo was found in 97 per cent. of the cases, in 80 per cent. of whom it was the first symptom. In some cases it was very mild; in others the patient could not walk straight, but staggered along as if under the influence of alcohol.

Short memory was found in 90 per cent. of cases; they could not remember how long they had been sick or what were their first symptoms; in many instances they lost their mind entirely. Twelve per cent. of my cases became insane. Sore mouth or some abnormal change in the mucous membrane was found in 80 per cent. of cases. In some instances the mouth was ulcerated; in others it was red and of a glazy appearance and felt, the patient declared, as if it were scalded.

Burning of the feet and legs from the knees down was found in 95 per cent. of cases, and in no instance did it extend above the knees nor in any was it confined to the feet alone.

An eruption or a history of an eruption was found in 94 per cent. of cases, 75 per cent. of whom were affected on the hands and arms alone, and 20 per cent. on other parts of the body as well; but in every case the eruption appeared first on the hands or arms.

All were more or less nervous; the poisons seem to attack especially the nerve tissue, hence some observers think it is a purely nervous disease. The oldest patient was seventy; the youngest twelve. Ninety per cent. of the female cases were snuff dippers, none of whom showed improvement until I had stopped the use of the tobacco, as it impaired their appetite to such an extent that they did not eat a sufficient amount to keep them properly nourished.

Twenty-four per cent. of my patients died; a large percentage of these were in the last stages when I saw them, and to some of them I gave no treatment at all; two I saw early in the disease, and they were in good condition, but the treatment seemed to have no effect on them.

I have tried almost everything in the way of treatment that I have ever heard of, and find arsenic the most efficacious in the way of drugs. Some have obtained good results with castor oil, and naturally so, for it cleanses the intestinal tract where I think the seat of the trouble lies. Others use colocynth, while yet others use irrigations of the colon, all of which remedies, for the reason assigned above, are good. Castor oil and bismuth in large doses with a diet of whole wheat bread, vegetables, and other food that leaves much residue, have given me best results in preventing the formation and absorption of these products from the intestinal tract. As to the administering of arsenic, it is immaterial which form of arsenic is used, the essential point being to give an amount sufficient to counteract the poisons. I have seen one patient who was apparently cured by taking fifty drops of Fowler's solution three times a day, but very few people can take by mouth enough arsenic in any form to do much good. Atoxyl and soamin in very large doses hypodermatically give the best results; soamin can be given in larger doses than atoxyl without toxic effect, and therefore is preferable. Salvarsan or neosalvarsan can be used and will give excellent results if a number of doses are given to each patient, but this makes the treatment very costly as well as dangerous.

Arsenic, it should be borne in mind, only eliminates the poisons already absorbed in the tissues of the body; it has no effect on the production of the poisons, and, unless the patient be placed on a proper diet so as to correct the intestinal fermentation, in the course of time the system will become saturated and the symptoms will return.

423 Fayetteville Street.

A PLEA FOR MORE CARE IN THE TREATMENT OF FOLLICULAR TONSILLITIS.

By WILLIAM LAPAT, M.D.,

NEW YORK.

I FULLY realize that the medical literature is overloaded with papers written on the tonsil and its diseases and that very little of this is new; nevertheless, I have the presumption to add to this literature an article on one of its supposedly most common and least dangerous of its diseases, with the idea in mind to emphasize that this disease is and always will be liable to dangerous sequelæ, and that more care should be taken in its treatment.

In most of the hospital dispensaries follicular tonsillitis is treated with very little respect; the patient is given a purgative or a gargle (sometimes both) and is told to return in two or three days. No warning is given as to the importance of staying in bed, and in fact the patient is made to feel that he is suffering from one of the very mildest of ailments.

We must remember that although at first this disease is a local infection, it is only a few hours before it becomes a general systemic affair, often lodging in the joints, causing an arthritis with sometimes a subsequent endocarditis. I have had in the past four years a number of cases of arthritis which came on during attacks of tonsillitis. The history of one of these cases, which resulted in an endocarditis, is as follows:

I was called to see M. M., a boy nine years old, who showed all the clinical symptoms of an attack of follicular tonsillitis. I saw him first on the third day and he was then developing pains in both knee-joints, which in twenty-four hours became a severe arthritis from which he suffered two and a half weeks and finally developed an endocarditis. This boy never gave any past history of rheumatism nor could I in any way account for the heart lesion except as a result of the arthritis which came on during his attack of tonsillitis.

Various observers have noted the close relationship between the tonsils and different infections of the body. Ballenger tells of two cases of endocarditis following a tonsillitis.

Wood says: "The rapid and marked systemic intoxication seen in cases of simple tonsillitis shows that some toxins at least are readily absorbed from the tonsil into the general circulation."

Emil Mayer says: "There is not yet sufficient evidence to prove that the tonsil is only or ever the chief portal of entrance for rheumatic poisons. Considering, however, that in all probability acute articular rheumatism represents a mild type of septic hematogenic infection of the joint, there is no reason why the tonsil with its notorious facility for infection with pyogenic germs should not, possibly even frequently, assume the rôle of an infected wound leading to septic consequences of a systemic nature."

Forchheimer, in his book on "Treatment," tells of an investigation of D. J. Davis in forty-five cases of rheumatism in which he found in the crypts of the tonsils pure or nearly pure cultures of a streptococcus, representing various strains, nearly all of which when injected into rabbits in small doses produced an arthritis and in large doses a septicemia.

If we regard the tonsil as a port for the entrance of various infections, even when the tonsil itself is not showing to the naked eye any special changes, that is, when it is not undergoing any process of active inflammation, surely much more are the chances for a systemic infection when we have a pathological condition as we do in follicular tonsillitis. Such being the case, I think it is important that we treat this infection with much more care and give our dispensary patients more explicit instructions with regard to the treatment, so that we may lessen as much as possible the danger of serious sequelæ.

Treatment.—For the past year and a half I have

been laying a great deal of importance on the early and active local treatment of this disease, looking upon it in the first few hours as a local infection and treating accordingly by applications which would tend to destroy the action of the bacilli. The drugs which have given me excellent results are hydrogen peroxide and a solution of the tincture of iodine, which is 5 per cent. stronger then the official tincture. A number of those cases which I have seen early I have been able to abort. The hydrogen peroxide I use on a cotton applicator to remove the patches from the tonsils, then with another applicator I apply the iodine into the crypts, taking care that none of it flows into the pharynx. These applications are made twice a day on the first two days, and at the same time the patient uses a spray of icthyol as follows:

Icthyolis,	8.0
Olei anisi,	0.2
Aqua anisi, ad.,	60.0

M. Sig: Shake well and use as a spray every two hours. This is a mixture used by Dr. J. Abraham of the Polyclinic and I find that it has an excellent effect on the reactionary inflammation in the mouth and pharynx.

The general treatment should be carried out as in any other acute infection; the patient must be put to bed and kept there until all symptoms have disappeared. Calomel is given at the outset, diaphoretics for the fever, and the various complications should be treated as they arise. It is especially important that one should be on the lookout for the slightest sign of joint implication, as most of the serious results have been due to this cause.

916 Southern Boulevard.

TWO CASES OF TREATMENT BY RADIUM EMANATION.

By FRANCIS E. PARK, M.D.,

STONEHAM, MASS.

These two cases are remarkable not only from the prompt benefit that was derived, but also from the fact that the patients were twins. The first one consulted me last December.

Case I.—The patient was a tall, well built man of 59 years, but much emaciated, and with the face of a constant sufferer. From 1881 to 1904 he was the "lead man" in a large chemical works, and from the constant inhalation of the fumes he became so badly poisoned by this mineral that he had to give up work. From that time until I saw him he had been an invalid and under constant medical observation. There early developed an arteriosclerosis associated with constant pain in the heart and head, with frequent exacerbations of each. Of late years the anginal pain had become so severe as to cause grave apprehension for his life. Over each eye was a pigmented spot, that would swell up quite perceptibly with the headaches. The arteries that could be palpated were hard to the touch, and the blood pressure ran from 220 to 240. Apart from the angina the heart was normal. For the first two weeks there was no noticeable improvement, then it came steadily. At the end of four weeks practically all the pain, pain that had been persistent for ten years, had stopped. The blood pressure was reduced to 160. At the end of ten weeks he went home, saying that he felt like a new man. He certainly looked and acted like one and now after five months the improvement has persisted, and he has gone back to work. The treatment consisted of subcutaneous injections of isotonic sea-water freshly charged with radium emanation, given at two-day intervals. Once in four days he had an intravenous injection of thorium X, which seems to act the same as the radium emanation, of 80,000 units. Daily he sat in a hermetically sealed room for two hours, breathing an atmosphere containing about 12 Mache units of radium emanation to the litre of air and drinking 60 c.c. of water, containing 180 Mache units, every fifteen minutes. Over the heart and forehead he wore constantly a pad containing a quantity of concentrated pitchblende; that is, pitchblende ore that had been subjected to intense heat for a long period of time, during which most of the mineral present except the radium was volatilized. There was also a small amount of iodine given by the mouth to help eliminate any lead that might be still in the system.

Case II.—A twin brother of the preceding. Previous history was that of a hard working healthy man, a foreman for 21 years in a large construction company. Seven years ago he fell from a derrick and sustained what was diagnosed as a hemorrhage of the cord. His legs were totally paralyzed for several months and he was confined to his bed sixteen months. Gradually he got around, but has never been able to work since that time. When he came into my office, he walked with a sort of shuffle, and steadied himself with a cane. He was unable to open and shut his hands except very slowly and could not entirely close them. If he wished to put his foot in a chair he would have to lift it bodily with both hands. On stooping, in the attempt to touch his hands to the floor, he would instantly grow dizzy and pitch forward. There was also a slight paralysis of the throat, which bothered him considerable in eating. He had been under treatment during this time, but had never got any help beyond what had very gradually come back. This man was under treatment six weeks and went out practically a cured case and has gone back to work. In general appearance he looks about ten years younger. He is able to walk easily without a cane, can stoop and touch the floor without becoming dizzy, the paralysis in the throat has entirely disappeared, and he can open and shut his hands with ease. The improvement began to show within a week of his initial treatment. This latter was very similar to that of his brother's (radioactive sea-water, thorium X, and the radium emanations).

These two cases were very striking ones to watch. Twins, both with apparently incurable affections, of many years' duration, apparently cured, and put back into the wage-earner ranks again.

Medicolegal Notes.

Liability for Substitute—Abandonment of Case.—In an action against a physician for injuries to the plaintiff's wife while confined in childbirth resulting from the defendant's furnishing an incompetent substitute, it was held that a physician is responsible for an injury done to a patient through the want of proper skill and care in his apprentice or assistant. Likewise partners in the practice of medicine are all liable for an injury resulting from the negligence, either of omission or commission, of any one of the partners within the scope of their partnership business. The theory upon which this holding is based is that partners in the practice of medicine are sureties for the faithful performance of their engagements by each of them.

It is also an established rule that a physician, responding to the call of a patient, thereby becomes engaged, in the absence of a special agreement, to attend to the case so long as it requires attention, unless he gives notice to the contrary or is discharged by the patient. He impliedly contracts that he possesses, and he is required to exercise that degree of knowledge, skill and care which physicians practicing in similar localities ordinarily possess, but he does not impliedly warrant a cure, and can be held as a guarantor of success only in virtue of an express agreement. If he makes provision for the attendance of a competent physician upon his patient, he may leave temporarily, but for the unwarranted abandonment of a case at a critical period resulting in increased pain and suffering on the part of the patient he will be held liable in damages.

In the present case it was held that the question whether the fact that the defendant expected to attend court on that day and had other pressing professional engagements to which he could not give his attention and at the same time attend the plaintiff's wife furnished a sufficient excuse for his failure to attend in person when called by the plaintiff was one for the jury.—Lee vs. Moore, Texas Court of Civil Appeals, 162 S. W., 437.

MEDICAL RECORD.

New York, August 29, 1914.

THE FIXATION OF POISONS BY THE CENTRAL NERVOUS SYSTEM.

THE subject of the selective affinity between certain poisons and the central nervous system is one that presents many points of interest, with respect not only to general pathology but also to the pathology of the nervous system. A number of observers have pointed out that in various types of intoxication the nervous system contains an amount of toxin greater than any other part of the body. Ogier and Skolosuboff demonstrated the presence of arsenic in the brain in cases of slow intoxication by this drug and the presence of a large amount of hydrocyanic acid in the brain and spinal cord in cases of rapid poisoning by this substance. Similar observations have been made with respect to lead and the anesthetics.

This subject has been approached from the viewpoint of the microbic poisons, particularly those produced by the diphtheria bacillus, in a series of investigations performed by Georges Guillain and Guy Laroche. The results of their studies were first reported five years ago when they described the fixation of the diphtheria toxin by nerve tissue. A comprehensive survey of this subject is presented by these investigators in *Le Progrès Médical*, July 11, 1914. In their original work they had shown that the medulla oblongata of patients who have died in the course of severe diphtheritic paralysis contains toxic substances that are not present in the case of individuals dying from other affections. The toxicity of the above substance was determined by the fact that emulsions of the medulla oblongata in physiological salt solution when injected into guinea pigs caused the death of these animals. There is a direct path of the diphtheria toxin from the pharynx by way of the nerves to the spinal bulb. The affinity between the diphtheria toxin and the nerves is a particularly close one. Thus these investigators in collaboration with Grigaut showed that if diphtheria toxin is brought into contact with nerve tissue the toxic properties imparted to the latter cannot be removed even after repeated washing with physiological salt solution. It was found that the phosphorized lipoids of the phosphatid group (lecithin, cephalin) have an intense fixing power with respect to this toxin, while the non-phosphorized lipoids, such as cholesterin, are entirely inactive in this respect. Diphtheria toxin when combined with nerve tissue undergoes a marked activation of its toxic properties, the period of inoculation of the experimental disease and the duration of the latter being considerably shortened.

The toxin of tetanus is likewise fixed by the nerve tissues, but is contrasted with the diphtheria toxin in one respect, namely, the nerve tissue of an animal or human being that has succumbed to tetanus, if inoculated into a laboratory animal, will not evoke the disease unless the amount of tetanus toxin present exceeds the amount that has been neutralized by the nerve tissue. Another distinguishing characteristic is the fact that the phosphorized and non-phosphorized lipoids, with the exception of protagon, possess but slight fixing power with respect to this toxin, while the albuminoids are strongly fixative. The clinical differences between diphtheria and tetanus are probably to be explained on the basis of the above differences: the diphtheria toxin which causes paralysis is fixed and activated by the phosphorized lipoids, while the tetanus toxin which evokes muscle spasm is partly fixed and neutralized by the protein substances.

The poisons of the tubercle bacillus are fixed and activated by the nerve tissues. Tuberculin when mixed with nerve tissue has its power increased as much as fourfold. This fact may serve to explain some of the phenomena of tuberculous meningitis. The adult or the child affected with the latter dies before a local defense has been set up. Frequently at autopsy on cases of tuberculous meningitis there are observed but few local lesions; there may be only a congestion of the meninges. The rapidity and intensity with which the convulsive and paralytic symptoms of tuberculous meningitis develop are to be attributed to the avidity with which the poisons of the tubercle bacillus combine with the nerve tissue, particularly in the regions of the medulla and the basal ganglia. It has been shown that in the nerve centers the tubercle bacilli are quickly destroyed. This bacteriolysis which is a mode of defense nevertheless sets free toxins which become more potent by being combined with the cells that are responsible for their liberation.

This subject is one of engrossing interest and eminent clinical importance, and many of its ramifications can only be hinted at. One may allude to the selective affinity of strychnine for the cells of the anterior horns of gray matter of the spinal cord, to the fixation of alcohol by the brain, to the avidity with which chloroform and ether combine with nerve tissue, and to the predominance of lead in the same tissue in cases of plumbism. Oxalic acid is likewise seized by the nerve tissue to a greater extent than by any other part of the body. The symptoms of anaphylaxis are to be attributed largely to the fact that the anaphylatoxins expend their virulence upon the nerve cells with which they combine.

Important from many viewpoints of internal medicine is the hypothesis that endogenous poisons may behave in the same manner as those mentioned above. Nervous symptoms such as paralysis, tremor, convulsions, contractures, delirium, etc., are probably the result of a fixation of toxic bodies by

the nerve centers. This is a conception of fundamental significance in psychiatry and deserves extended investigation.

THE ETIOLOGY OF ACUTE ARTICULAR AND MUSCULAR RHEUMATISM.

Poynton and Paine and others a number of years ago called our attention to a specific streptococcus which they believed to be the cause of that much diagnosed and much abused condition known as rheumatism. Many other investigators, however, failed entirely to isolate streptococci from the joints, while others only rarely succeeded in finding them there present. As a natural consequence of these negative findings this view of Poynton and Paine failed to receive general acceptance.

More recently Rosenow (*Journal of Infectious Diseases*, xiv, 1, 61) claims to have isolated three types of organisms from the joints in rheumatism, and to have demonstrated that each of these could be transformed or transmuted into any of the others with considerable ease by modifying the environmental conditions. From the cases in which there was no muscle involvement he isolated two types of organisms—one a very long chain producer, the other resembling a micrococcus. These two types, after inoculation into animals, generally produced arthritis, endocarditis, and pericarditis, but as a rule no visible myocarditis and never a myositis. The third type of organism was a diplococcus in short chains, isolated from cases of rheumatism with definite muscular involvement. This organism also produced arthritis, endocarditis, and pericarditis, and more particularly myocarditis and myositis. From a study of the cultures in man and of the results of animal experimentation, Rosenow inclines to the view that acute articular rheumatism is due to streptococci which have peculiar properties, and that muscular rheumatism (or "rheumatic myositis") is caused by streptococci which are quite intimately related to those found in joint rheumatism.

Although Rosenow favors the retention of the name *Streptococcus rheumaticus* for the present, since the streptococci which produce the symptoms and lesions of rheumatism have certain specific features sufficiently distinct to distinguish them from streptococci from other sources, yet it must be understood that the so-called *S. rheumaticus* does not always produce rheumatism. Rosenow found that when first isolated these organisms had an affinity for the joints, the endocardium, and the pericardium, and frequently also for the myocardium and the muscles, but that this affinity tended to disappear on cultivation though it could be restored by animal passage. Moreover, it was observed that under certain conditions other strains of streptococci would assume the characteristics of the strains of streptococci isolated in cases of rheumatism. Rheumatic strains of streptococci might acquire the cultural characteristics of hemolytic streptococci, at the same time losing their affinity for the endocardium and pericardium but possessing an even more marked affinity for the joints. It was furthermore found that rheumatic strains may apparently be converted into pneumococci of a certain grade of virulence so as to produce, following intravenous injection, pulmonary hemorrhage and pneumonia, and even death from pneumococcemia. For these reasons Rosenow suggests the possibility that "previous to an attack of rheumatism various types of the streptococcus group, especially hemolytic streptococci, may acquire in the tissues of the infected individuals the features which give them the simultaneous affinity for joints, endocardium, pericardium, and myocardium."

This investigator also seems to have demonstrated that *Streptococcus viridans, S. mucosus, S. hæmolyticus, S. rheumaticus*, and the pneumococcus can be transformed one into the other by the experimental modification of environmental conditions *in vitro* and by injection into and passage through animals. It is in the tonsils, the various sinuses, the appendix, and about the gums and the teeth that such transformation is most apt to take place. Thus, assuming the truth of Rosenow's claims, not only should the importance of focal infections as an atrium for bacteria be appreciated, but we must also recognize that these foci further serve as places where bacteria may take on new properties and virtually become transformed into microorganisms of another kind, representing a more virulent strain. It is to be particularly noted that the strains from muscular rheumatism, more especially after one or two animal passages (and this applies also to other streptococci which have become equally virulent), show a decided affinity for the mucous membrane of the stomach, the pelvic mucous membrane, the medullary portion of the kidney, and the gall-bladder, the proof of this being given in the finding, in dogs and rabbits injected with these strains, of ulcer of the stomach, so-called "ascending" nephritis, and cholecystitis with beginning gallstone formation.

The International Red Cross.

It is a singular coincidence that the eve of one of the greatest battles of modern times was also the fiftieth anniversary of the signing of the Geneva Convention which inaugurated the International Red Cross movement. For it was on August 22, 1864 that there was terminated the conference whose object was "the relief of the wounded of the armies in the field." It was Henry Dunant in his "Souvenir de Solferino" who first suggested the idea of creating in times of war auxiliary societies for the relief of the wounded. At the call of the Society of Public Utility of Geneva an international conference met in that city in October, 1863, and formulated a set of resolutions which established that wonderful humanitarian movement which forms the bright background in the dark picture of modern warfare. In order that these resolutions might have the force of a treaty a diplomatic conference met in Geneva at the request of the Swiss National Council under the patronage of Napoleon III. The representatives of twelve nations signed the famous pact which has since been known as the Geneva Convention. Too well known to need repetition is the story of the remarkable growth of the Red Cross movement which received its official impetus on that day—the movement which has enlisted the cooperation of every

nation on the globe, and which has extended its sphere of usefulness beyond the battlefields of war to scenes of famine, of pestilence, and of industrial disaster. It may be of interest to Americans to know that the Geneva Convention was signed in the hall which was later named the "Hall of the Alabama" after the court of arbitration which met to settle the *Alabama* claims which had been a bone of contention between Great Britain and the United States. France was the first nation to become a signatory to the Geneva Convention and although the United States had taken part in the original conference, it did not ratify the action of its representatives until 1882. The last nation to fall in line was Ecuador in 1907. In the meantime the articles of the Convention of 1864 were superseded by those of the Convention of 1906, of which the United States had the honor of being the first signatory. Apart from participation in the International Red Cross the different nations have established their own national Red Cross organizations, the first of which was founded in Würtemberg in 1863. The American organization was born in 1866. The worldwide efficiency of the latter needs little comment. Of the contributions made to the Red Cross funds for the relief of the wounded of the five nations that took part in the Balkan Wars of 1912, the largest sum of money came from the United States.

Successful Treatment of Tetanus Neonatorum

The undoubted power of magnesium sulphate as used by intraspinous injections over the convulsions of tetanus is offset by the fact that death may still occur from severe complications, which may well be ascribed in part to the paralyzing action of the drug. Attempts are naturally being made to neutralize the overaction of the magnesium. Before the Pedriatic Section of the Verein für innere Medizin und Kinderheilkunde, Berlin, which met last July (*Berliner klinische Wochenschrift*, July 27) Falk reported three cases of tetanus neonatorum, seen within four months, in all of which recovery ensued. The solution of magnesium sulphate employed varied from 8 to 25 per cent. To offset the paralyzing action chlorate of calcium was injected. In discussion Finkelstein added that the duration of the disease was not diminished, but the treatment certainly prevented the violent convulsions which often terminate life suddenly and, moreover, gave opportunity to push nourishment while the jaws were relaxed. Falk stated, that feeding must be done early, and that one must be sure that the magnesium has not caused deglutition paralysis. Late feeding might set up spasms.

News of the Week.

To Muzzle Dogs.—As the result of numerous complaints made recently and the death of a boy from rabies in Bellevue Hospital last week, the Department of Health has ordered that all dogs in New York City must be muzzled, the order to become effective on September 15.

Typhoid Fever on Hart's Island.—An outbreak of typhoid fever among the prisoners on Hart's Island, New York, has made it necessary for the Department of Health to assume control. The city reformatory for boys and a branch of the workhouse are situated on the island, and the inmates number about 800. During the first two weeks of August 15 cases of typhoid fever were reported, and investigation showed that some of the patients had picked vegetables from a garden near the potter's field on the island, and that others had eaten clams found on a beach contaminated by sewage. The Health Department will inoculate all of the inmates with anti-typhoid serum.

Call for Nurses.—The American Red Cross on August 15 sent out its first call for nurses to join the relief expeditions which it is preparing to send to Europe. Great Britain, France, and Russia, through the American embassies in those countries, have already formally accepted the offer of surgeons, nurses, surgical equipment, and hospital supplies, from the Red Cross. One of the Red Cross units will also be sent to Servia.

Decrease in Infant Deaths.—Notwithstanding the extreme heat during the week ending on August 22, the number of deaths of infants under one year was four less than that for the same week of last year. In the Borough of Manhattan the deaths were increased by eleven, but in both Brooklyn and Queens there was a decided reduction. The total number of deaths was 346.

Beef Tuberculosis Board.—The commission authorized by the New York State Legislature to undertake the scientific study of the causes of bovine tuberculosis, its economic and health effects upon the State, and to report its findings to the Legislature, with recommendations, has been appointed by Governor Glynn. An appropriation of $5,000 is available to defray the expenses of the commission, which, at the Governor's request, will meet and organize as soon as possible. The members of the commission are as follows: Dr. Theobald Smith, Director of the Division of Animal Pathology, Rockefeller Institute; Dr. Hermann M. Biggs, Commissioner of Health, State of New York; Dr. Linsly P. Williams, Deputy Commissioner of Health, State of New York; Dr. Philip Van Ingen, of the New York Milk Commission; Dr. Henry L. K. Shaw, Professor of Children's Diseases, Albany Medical College; Henry H. Law, of Briarcliff Manor; Seth Low; Prof. Veranus A. Moore, of Ithaca, Dean of the New York State Veterinary College, Cornell University; Calvin J. Huson, New York State Commissioner of Agriculture; A. L. Brockway, of Syracuse; Prof. H. E. Cook, Dean of the New York State School of Agriculture at Canton; W. H. Vary, of Watertown, Master of the State Grange; Albert Manning, of Otisville; V. Everit Macy, of Ossining; H. J. Wright, editor of the New York *Globe;* James A. D. S. Findlay, of Salisbury Hills; Judge O. U. Kellogg, of Cortland; Edward Van Alstyne, of Kinderhook, Director of the Farmers' Institutes in the State Department of Agriculture, and Henry L. Best, of West Sand Lake.

The Long Island State Hospital for the Insane, Brooklyn, which has heretofore been leased from the City of New York by the State of New Yohk for the nominal figure of $1 per year, since the State Care Act went into effect in 1895, was transferred by deed from the City of New York to the State of New York on August 10.

"Twilight Sleep" Hospital.—It is rumored that plans are under way in New York for the erection of a hospital in the Bronx where maternity cases can be treated by the so-called Freiburg method of inducing "twilight sleep" during labor.

American Electro-Therapeutic Association.—The annual meeting of this association will be

held at Battle Creek, Mich., on September 15, 16, and 17, 1914, under the presidency of Dr. George E. Pfahler of Philadelphia. Details as to the programme and the exhibit of physiotherapeutic apparatus which is being prepared may be obtained from the secretary of the association, Dr. J. Willard Travell, 27 East 11th street, New York.

Personals.—Dr. JAMES M. JOBLING, assistant professor of pathology at the College of Physicians and Surgeons, New York, and formerly pathologist to the Michael Reese Hospital, Chicago, has been appointed professor of pathology at Vanderbilt University, Nashville, Tenn.

Dr. ALEXIS CARREL will, it is now reported, be made director of the Military Hospital of Lyons, France, throughout the war. Last week it was rumored that he had already gone to the front with the French army.

Dr. JOHN E. B. BUCKENHAM, first assistant resident physician in the Philadelphia Municipal Hospital for Contagious Diseases, has been appointed acting superintendent, vice Dr. Wm. H. Walsh, who has been granted a month's leave of absence prior to assuming the duties of medical superintendent of the Children's Hospital.

Obituary Notes.—Dr. JAMES ROBIE WOOD of New Brighton, N. Y., a graduate of the Bellevue Hospital Medical College in 1867, a surgeon in the Confederate Army during the Civil War, and formerly in charge of the Ward's Island Hospital, New York, died on August 9, on board the United States transport *Logan*, while en route from Manila to San Francisco, in his 77th year.

Dr. CHARLES SEGERLUND, of Caledonia, Ill., a graduate of the Bennett Medical College, Chicago, in 1897, and a member of the American Medical Association, and the Illinois State and the Boone County Medical Societies, was struck and instantly kiled by a railroad train at Caledonia on July 24, aged 47 years.

Dr. THOMAS E. HEENAN of Philadelphia a graduate of the Medical Department of the University of Pennsylvania, but for many years past in the diplomatic service of the United States, and recently consul-general at Fiume, Hungary, died at his post, from heart disease, on June 26.

Dr. ROBERT P. PAGE of Berryville, Va., a graduate of the Medical Department of the University of Pennsylvania, Philadelphia, in 1861, a surgeon in the United States Army during the Civil War, died at his home on July 27, after a short illness, aged 76 years.

Dr. CHARLES P. GARLAND of Rock Island, Va., a graduate of the Hospital College of Medicine, Louisville, Ky., in 1891, died recently at the Tucker Sanatorium, Richmond, from pellagra, after a long illness, aged 47 years.

Dr. HENRY KNOX STRATFORD of Chicago, Ill., a graduate of the Eclectic Medical College of Pennsylvania, Philadelphia, in 1865, died at his home on July 28, aged 93 years.

Dr. WALTER FREDERICK APPLETON of Passaic, N. J., a graduate of the New York Homeopathic Medical College and Hospital in 1906, died at White Haven, Penn., on July 30, aged 35 years.

Dr. JACOB JACQUES FABIAN of Grand Rapids, Mich., a graduate of the University of Tennessee, Medical Department, Memphis, in 1907, and a member of the Michigan State and Kent County Medical Societies, and secretary of the latter, was drowned while bathing at Ottawa Beach, on July 28, aged 30 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

CLINICAL CONGRESS OF SURGEONS OF NORTH AMERICA —INTERNATIONAL DENTAL CONGRESS.

LONDON, August 7, 1914.

THE Clinical Congress of Surgeons of North America has come to London for the celebration of its fifth annual session, which I think may be pronounced a great success. The meetings were numerously attended by enthusiastic members. But the great feature of this congress is not theoretical discussion but the visiting of surgical wards of hospitals and here that method of studying one another's clinical work was duly carried out by a number of our general and special hospitals. We were able to show also a number of cases illustrating the after history of patients who had been subjected to serious and special operations. Sir Rickman Godlee delivered an address of welcome and invited the visitors to inspect the Hunterian Museum, which they were actually eager to do. At the Royal College of Surgeons a lecture was given by Mr. S. G. Shattock on the origin and growth of tumors and the visitors seemed glad to hear him state the views he holds on cancer. He repudiates the common belief as to its hereditary character. Further he insists that it is not transferable from one person to another, though he admits it may perhaps be transferred from one part of the body to another part of the same patient; that is, he cannot dispute the possibility of autoinoculation. Many cases of cancer were seen in the course of the visits to the hospitals and operations for it witnessed. The skill of our surgeons in dealing with this and other diseases has been fully acknowledged and, I may say, admired. At the Westminister Hospital there was quite an exhibition—excision of mammary cancer, laperatomies, removal of part of stomach and of various abdominal and other tumors. At the London Hospital the whole of the stomach was, I am told, removed and a pouch of the alimentary canal arranged to serve as a substitute. But interesting as the rarer cases were the more general ones were perhaps on the whole better subjects for observation of the British methods, and J. B. Murphy on taking the chair referred to the difficulty of organizing a meeting at such a distance, but was glad it had been done as it gave so clear an impression of British surgery and those who practiced it. He believed the Congress would increase their admiration for each other's work and their realization of the brotherhood of science throughout the world.

Dr. Wm. Rodman, president-elect, expressed the satisfaction of the Congress at visiting London and conveyed cordial greetings to the British profession. A great number of papers were read and some elicited very instructive opinions and experiences. Among them Prof. V. Eiselberg's on the choice of operation for gastric ulcer, which was discussed by Watson Cheyne and James Sherrin; the former had himself an allied paper. Professor Schmiegelow related his results of operation for intrinsic cancer of the larynx. Sir St. Clair Thompson gave his experience of laryngo-fissure. Hyperthyroidism was well discussed *à propos* of a paper by Dr. Mayo of Rochester on the primary and late results of operations for this condition.

The Sixth International Dental Congress met

here on the 4th inst. In this as in other meetings the outbreak of war has had a marked effect. A dutiful message to the King was sent and one of thinks to the government regretting that the President of the L. G. B. who was to have been present was prevented under the changed circumstances. Mr. Howard Mummery, president, gave an address in which he touched on questions of medical interest. Caries, he believed, was a preventable disease, but only by the co-operation of government, medical men and the public—not a very costly event, I think. As to treatment there were two schools, one advocating the preservation, the other the removal of all diseased teeth. He regarded a hard and fast rule as a mistake. The state dealt with diseases which threatened life directly, but made no provision for the more subtle courses of degeneracy.

Mr. Paterson of the International Dental Federation lamented that war had deprived the Congress of so many delegates from European countries, but war could not stay the progress of dental science or destroy the friendship of its votaries and their efforts for the benefit of humanity.

Representatives of the Australian Commonwealth, of New Zealand, Canada, Argentina, Finland, Greece, Italy, Mexico, Russia, Spain, Japan, Sweden, Egypt, Hungary and the United States took part in the proceedings. The president said the government was unable to give the entertainment which had been arranged for and the usual banquet had been abandoned. The scientific addresses by representatives of French and German dentistry could not be given. Dr. E. C. Kirk of the University of Pennsylvania, however, dealt ably with the tendencies of dental education, holding that the scope of character of the special dental curriculun must be improved to meet the demands of modern education. Dr. W. Guy of the Edinburgh school and president of the British Dental Association gave an address on "Narcosis." He said the man who gave chloroform for dental operations was either ignorant or deliberately sinning against light, as ether was less dangerous. For prolonged operations nitrous oxide and ether, in mixture or in sequence, was of value and with the addition of oxygen still better. A mixture of nitrous oxide with oxygen ought to supersede all and it was the urgent duty of all anesthetists to become expert in its administration.

OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

TREATMENT OF LEPROSY—COCCIDIOSIS IN CATTLE—IMPROVED HEALTH CONDITIONS IN MANILA—CONTROL OF THE PHILIPPINE GENERAL HOSPITAL NATIVE GRADUATE NURSES.

MANILA, P. I., July 11, 1914.

THE regular meeting of the Manila Medical Society was held at 8:30 P.M., Monday, July 6, in the College of Medicine and Surgery. The first paper read was by Dr. Heiser upon the treatment of leprosy with a mixture of Chaulmoogra oil, resorcin, and camphor. He stated that nothing especially new was claimed for the treatment but that the results up to the present time show that it has the apparent effect of arresting the disease regardless of its type in almost every instance. Statistically, the results of the 9 cases which he reported were as follows: Apparent cures, 11.11 per cent.; apparent clinical recoveries, 44.44 per cent.; showing marked improvement, 33.33 per cent.; showing only slight evidence of improvement, 11.11 per cent. The prescription used is the following: Chaulmoogra oil, 60 c.c.; camphorated oil, 60 c.c.; resorcin, 4 gm. Mix and dissolve with the aid of heat on a water bath, and then filter. He gave the following details as to the treatment: The injections are usually made at weekly intervals, in ascending doses. The initial dose is 1 c.c. and this is increased to the point of tolerance. Much difference exists among the cases as to the amount of the mixture which they are able to take. In some cases a few cubic centimeters produce marked reactions in the lesions accompanied by fever and cardiac distress. Sometimes it is better to reduce the amount of the dose and inject at more frequent intervals. The object sought is so to regulate the dose as to prevent reactions of too violent a character. Quicker results are also apparently obtained when it is possible to inject the mixture into large leprous deposits or to divide the dose by injecting it into a number of smaller infiltrations. Experience so far leads to the inference that with additional study the prospects seem fair for greatly improving upon the results that are obtained at present. Attention is drawn to the fact that no strychnine was used. Many writers have regarded it as an essential part of the Chaulmoogra oil treatment. Saline purgatives are freely employed. Two per cent. hot sodium bicarbonate tub baths are prescribed every other day. Those who take prolonged baths regularly seem to improve more rapidly than those who do not. Dr. Heiser drew especial attention to the fact that it was important to remember that there are many treatments for leprosy which apparently cause some improvement, and it not infrequently happens that when cases of leprosy are placed under better hygienic conditions and have hospital care, or for other reasons not understood, that often the disease is arrested, in a few instances improvement results, and that apparent cures may take place without any treatment.

The next paper read was entitled "Clinical Observations on Coccidiosis in Cattle and Carabaos," by Dr. C. H. Schultz. Dr. Schultz showed cultures of the organism which he had found in the cattle of the Philippines and gave much clinical detail as to the differential diagnosis between rinderpest and coccidiosis. He stated that the mortality from coccidosis was apparently as great as from rinderpest and no doubt was frequently mistaken for that disease. He further said that its spread was perhaps principally due to infected water supplies.

The improvement in Manila's death rate still continues. During the month of June the very low rate of 17.65 per thousand was reached, which was very much lower than any mortality which has been reported since the American occupation of the Philippines and when contrasted with the mortality of 44.28 per thousand of June 10 years ago may be regarded as an index of the improvement which has been brought about in the health situation.

The controversy as to whether the Philippine General Hospital should be transferred from the control of the Bureau of Health to the College of Medicine and Surgery of the University of the Philippines has apparently been definitely settled. The Secretary of the Interior held both public and private meetings and went into the question at length with the result that the Hospital is to continue as a division of the Bureau of Health, and the College of Medicine and Surgery is to be re-

lieved of the treatment of government employees and pay patients. One hundred or more beds are to be available for teaching purposes. There has also been created an advisory board to be composed of prominent citizens who are to assist in settling administrative questions which arise in connection with the hospital. It is hoped that this board will prove useful in disseminating information among the public with regard to the functions of a modern hospital. The Philippine General Hospital was organized on a thoroughly modern basis but when it is remembered that the public of the Philippines has had very little experience or opportunity to become familiar with the objects and purposes of a large general hospital, or the customary rules by which such institutions are governed, it is not strange that misunderstandings should occur from time to time.

There has been a gradual extension in the employment of graduate Filipina nurses to assist provincial health officers in the discharge of their duties. The results, for instance, in the province of Cebu have been very satisfactory and the nurses have been of great assistance in disseminating useful information. They have been of great assistance in the management of a "Gota de Leche" depot for the distribution of safe milk; in giving public lectures and practical demonstrations in the homes of the people of how bacillary dysentery may be avoided; in settlement work, etc. A provincial nurse is on duty in Samar and arrangements have been about completed for the employment of similar nurses in the provinces of Albay, Ambos, Camarines, and Bulacan. Within the next few weeks it is proposed to detail nurses to health stations in the city of Manila in order that they may give practical demonstrations in the homes of the people with regard to infant hygiene and other sanitary matters.

FIFTH ANNUAL SESSION OF THE CLINICAL CONGRESS OF SURGEONS OF NORTH AMERICA.

(From Our Own Correspondent)

LONDON, July 30, 1914.

AMONG the many splendid papers read at the Congress, none was more practical and valuable than that of Dr. George E. Armstrong of Montreal. The subject chosen by Dr. Armstrong for discussion was typhoid perforation and some highly instructive points were brought out. As was the case at all the sessions, the session on Wednesday evening, July 29, was fully attended and the papers read were followed with keen interest. Dr. Armstrong commenced by pointing out that in the two provinces of Quebec and Ontario in Canada there were during the five years 1908-1912 inclusive 6,011 deaths from typhoid fever, an average of 1,202 deaths per annum. In the province of Alberta during the five years 1908-1912 inclusive there were 852 deaths from typhoid fever, an average of 170 per annum. In the United States of America during the four years 1909-1912 inclusive there were 45,833 deaths from typhoid fever, an average of 11,458 deaths per annum. The average death rate was a little over 20 per 100,000 of population. Dr. Armstrong went on to say that the responsibility for the enormous waste of human lives could not be laid at the door of the medical profession. It was a reflection upon the humanitarianism and business acumen of the laity in these countries. It had again and again been proven to a demonstration that pure water and efficient drainage prevented typhoid. Typhoid could be arrested by an Act of Parliament and by municipal legislation. Regarded as a purely economic question the money spent in removing the causes of typhoid would earn larger dividends than if invested in the best bonds in the world. Why should not municipalities, towns, and cities be made as responsible financially for the loss of time and loss of life from a preventable disease like typhoid as were the transportation companies by land and water made responsible for preventable accidents? However, typhoid was still with us, and was still attended by a mortality from several complications, 75 per cent. of which were surgical.

As for prognosis, attention was drawn to the fact that a typhoid perforation not closed by the surgeon was almost always a fatal complication. Emphasis was laid upon the need for early diagnosis, and the diagnostic symptoms mentioned in Choyce's "Surgery" and Howard's "Practice of Surgery" were criticized as inaccurate. According to Armstrong the first indication that a perforation had occurred was usually pain. And an important point in the training of a typhoid nurse was to teach her to send for the interne whenever a typhoid patient complained of abdominal pain. In 25 per cent. of cases not having pain at onset the following conditions were found: In 11 per cent. toxemia obscured all signs; in 4 per cent. the condition was obscured by severe concurrent hemorrhage; 4 per cent. were not diagnosed; 1 per cent. had chills; 2 per cent. had rigidity, and 4 per cent. had vomiting. The symptom that Armstrong would place second because of its constancy and significance was change of expression. This change of expression was manifested in a picture of suffering from pain, a sudden pallor, a change from a feeling of comfort to that of distress, restlessness, cardiac failure, vomiting, painful defecation, loss of rallying power after hemorrhage, a chill, profuse sweat, general malaise, an unaccountable change for the worse in the general condition, or sometimes a feeling on the part of those in attendance that something had happened that they could not account for. Tenderness was present in some degree in 88 per cent. of the cases and absent in 12 per cent. Eighty-five per cent. of the cases showed distinct rigidity and 15 per cent. did not.

Little or no value could be attached to the absence of liver dullness. If the area of liver dullness had been noted from day to day and then suddenly disappeared in association with abdominal pain, it was significant. It was valueless in a distended abdomen. It was obliterated in 45 per cent., unchanged in 15 per cent., and not mentioned in 39 per cent. The fall in temperature so often spoken of rarely occurred. Occasionally there was a fall of one or two degrees in six or eight hours, but only in a few cases did any spectacular drop, such as from 103° F. to normal, take place. The pulse changes were always clear. A sudden change from slow and good volume to rapid and small often occurred. In 95 per cent. of the cases the pulse quickened. Of the change in blood pressure he could not speak. Those who had seen many typhoid perforations would appreciate Fitz's statement that perforation of the intestine in typhoid fever might take place without any suggestive symptoms, and that suggestive even so-called characteristic symptoms might occur without any perforation having taken place.

The following were the symptoms which in Arm-

strong's opinion called for immediate incision, or rather were the minimum of signs that might demand surgical intervention: Persistent pain, definite change for the worse in the expression of the patient, tenderness, either abdominal or rectal, rounding up of the abdomen, and increased resistance to pressure. If these symptoms were present, even if the temperature and pulse were not decidedly altered nor vomiting present, the likelihood of a perforation was very great.

Local anesthesia, it was pointed out, had very materially altered our attitude towards early operations. It was no longer necessary to administer a general anesthetic. The closing of a typhoid perforation was one of the simplest operations in surgery, one that could be quite well performed by any one capable of carrying out a perfect surgical technique. After describing his own mode of operation, Armstrong laid stress on the point that the percentage of recoveries was gradually increasing. In the Royal Victoria and Montreal General Hospitals, 140 perforations had been closed and 38 had recovered, or 27.14 per cent. The paper concluded with the expression of opinion that an important point was to let the house staff of a hospital feel that it was a reflection on their professional attainments to overlook a perforation. When once they really appreciated that fact cases were sent to the operating room promptly.

Sir Anthony Bowlby of London, in discussing this paper said that he had gained a considerable amount of experience of typhoid and its surgical accidents during the South African war. He held the view that most cases of supposed recovery after perforation without surgical treatment were not really cases of perforation; perforation was almost invariably fatal without operation. Early diagnosis which could generally be obtained and prompt operation should be the routine treatment. The difficulty of diagnosis was in direct proportion to the severity of the illness. A patient stupified by toxemia could not describe his symptoms. More than half of all the cases of perforation were not given a chance of operation. He mentioned among the premonitory symptoms large sudden hemorrhages as conducing to the liability of perforation. Pain, often very sudden, severe, and diffuse over the whole abdomen was an important symptom in proportion as the patient was mentally alert, nor was its abeyance to be taken as a restorative sign. A blood count should be made two or three times a week as part of the routine examination in typhoid fever. A sudden rise in white cell count suggested the onset of some inflammatory lesion. He agreed with Dr. Armstrong on the importance of observing the patient's expression, for even if the patient were unconscious he showed a restlessness after perforation contrasting strongly with his previous lethargy. A rigor after the second week should always excite suspicion. The point was earnestly emphasized that perforation might be multiple, therefore the surgeon should not be content with discovering and dealing with a single perforation.

The next paper read was also of exceptional value and interest. It dealt with hyperthyroidism from a surgical standpoint, and although the views of the author, Dr. C. H. Mayo, are probably known to a large proportion of the American medical profession, to the English part of the audience in the Cecil Hotel on the evening of July 24, many of the theories and facts concerning hyperthyroidism expressed by the distinguished Rochester surgeon were more or less new. Moreover, the subject was presented in a singularly attractive manner, if it were allowable to use such an expression in referring to a surgical subject. Dr. Mayo did not read from manuscript, but in an easy and natural way discoursed of the matter from several aspects. He pointed out that the term "hyperthyroidism" was so expressive of a group of symptoms, the symptom-complex of which has been seen and described under various names in all countries, that it was chosen as the title of the study.

In discussing hyperthyroidism the following points were noted: (1) Practically all cases of clinically true exophthalmic goiter showed marked primary hyperthrophy and hyperplasia of the parenchyma of the thyroid. Furthermore, the clinical stage of development of the disease was paralleled by the stage of development of the pathological condition in sufficiently marked degree that one might estimate the clinical condition from the pathological examination with about 80 per cent. of accuracy. The degree of severity of the clinical condition was similarly paralleled by the pathological condition of the gland. The relationship between hypertrophy and hyperplasia of the thyroid and the clinical symptoms of true exophthalmic goiter was remarkably constant. (2) While a mild degree of hyperthrophy and hyperplasia within physiological limits might be present in the gland, particularly in the young and during pregnancy, yet the absence of this condition in the thyroids of adults coming to operation for toxic, nonexophthalmic, and nontoxic goiters was most striking. Without making any allowance for either clinical or pathological errors of diagnosis, less than 1 per cent. of all cases coming to operation for goiter showed any considerable primary hypertrophy and hyperplasia of the parenchyma of the thyroid except as associated with clinical symptoms of true exophthalmic goiter. (3) The pathology of atoxic simple goiter was marked essentially by atrophic parenchyma, decreased function and decreased absorption. The process was a chronic one. (4) The pathology of toxic nonhyperplastic goiter of Plummer's clinical group 2, that is, those resembling exophthalmic goiter, was one of increased parenchyma through regenerative processes in atrophic parenchyma or the formation of new parenchyma of the fatal type with an increase in each instance of secretory activity and of absorption. The process was a chronic one, but sufficiently active to cause the patient to consult a surgeon earlier than did those in clinical group 1. (5) The nearer the cases of clinical group 2, toxic nonhyperplastic, approached in age and symptoms true exophthalmic goiter the shorter the duration of the period of goiter before operation and the smaller the average weight of the gland at the time of its removal. (6) The cases of toxic goiter of clinical group 1, that is, those in which the symptoms were of the cardiovascular variety, much more closely resembled cases of simple goiter in their pathology in all respects than did the cases of clinical group 2. A larger number of them were of the colloid goiter type; the enlargement of the thyroid had existed for a longer period before operation and the portion of the gland removed was materially larger than in those cases of clinical group 2. (7) Finally, it might be stated that all the above pathological evidence pointed to a constant relative association of increased secretion and increased absorption from the thyroid proportional to the degree of

toxicity on the part of the patient. There had been as yet no absolute proof that such secretion and absorption were the causes rather than coordinate with the symptoms, but the evidence presented strongly pointed to that conclusion. In answer to the question: What caused an oveactivity of the thyroid? it was possible that the condition might arise from extra demands made upon the gland in its capacity for nutrition or defence in toxic conditions. Possibly in its latent sex relationship such demands might be temporary or long continued. For a time the excess secretion might be neutralized. When shock was regarded as the cause of the sudden onset of hyperthyroidism it was often only an evidence that the equilibrium of the nervous system had been upset in the presence of a latent hyperplastic thyroid, thus producing the sudden symptoms which had previously been controlled or neutralized. It was stated that up to June 15, 1914, 6,868 operations had been performed for goiter in St. Mary's Hospital, Rochester. Of these, 3,295 had been performed upon patients with hyperthyroidism.

Mayo was of the opinion that the various types of goiter should be treated both medically and surgically. Exophthalmic goiter was essentially a disease of a chronic character, presenting exacerbations and ameliorations of symptoms extending over a period of months or several years. After the first year the gland often underwent a regression. However, while the disease was amenable to medical treatment by the removal of a large amount of the hypersecreting gland it was by no means urgent surgery, and all patients during periods of exacerbation should be considered as medical cases. The technics of operative procedure of ligation, sympathectomy and thyroidectomy were described and then the fact was referred to that the great lowering of mortality following operation for exophthalmic goiter was due less to trivial details of technique than to better judgment in the preparation of patients, the selection of a time, type and extent of operation, and its division into stages, with varying intervals of rest. The high mortality of the past was no longer a determining factor against surgical treatment. As many as 275 consecutive operations had been made on the thyroid between deaths occurring from the operation. The average operative mortality at present probably varied from one to three per cent. Relapse of some degree occurred in a small percentage of cases through the removal of too small an amount of the thyroid. Such cases should be reoperated upon.

Mayo concluded his paper by a reference to the effect of pregnancy upon the disease or following the operation. A few of these patients were in much better health during pregnancy; however, in the majority the symptoms were worse. He believed that the risk to life incident to pregnancy and labor was less than from abortion, which rarely should be produced, since most of such patients improved after child birth.

Mr. James Berry of London said that he would speak chiefly on the clinical side of hyperthroidism. His experience had been in hundreds and not in thousands as had been that of Dr. Mayo. He had done 966 operations for the removal of goiter, or adding operations for ligation of thyroid arteries, somewhat more than 1,000. For some time he had been opposed to operating upon exophthalmic goiters, but experience and improvements in technique and in methods of producing anesthesia, especially local analgesia had changed his views, though even now he was careful as to the selection of cases. Dr. Mayo had emphasized the need to avoid operations during mental irritability, muscular weakness and acute cardiac dilation. In many severe cases, however, it was unnecessary to perform the larger operations as ligation of a superior thyroid artery was not only a safe but a satisfactory procedure whether preliminary to subsequent thyroidectomy or not. Berry divided cases of hyperthyroidism for practical purposes into (1) those with the classic symptoms and (2) ordinary goiters on which any one or two of these symptoms might be grafted. The second class could be cured by operation with little risk. He had performed 215 operations for hyperthyroidism since 1912. In his Lettsomian lectures he had recorded his experience up to that time. Of the 215 operations 82 had been for true exophthalmic goiter with one death and there had been two deaths among the other 173. In the cases of ligation of the thyroid no deaths had occurred.

1. Remarks Upon the Effects Observed in the Use of Mixed Toxins (Coley) in Certain Cases of Sarcoma. T. W. Harmer.
2. On the Diagnosis of Incomplete Forms of Pyloric Stenosis by Means of the X-Ray. F. H. Baetjer and J. Friedenwald.
3. Easily Made Dialyzer for Abderhalden Test. H. Greeley.

1. Coley's Mixed Toxins in Sarcoma.—T. W. Harmer concludes that the treatment of primary or recurrent inoperable sarcoma with mixed toxins must be intensive. The severity of the reactions may be lessened by certain measures and the author sees no contraindication to the treatment. The increment of dose and the interval between injections require some experience, but even after a considerable experience this method of treatment is always uncertain. Indeed, it is so uncertain and distressing that its institution is unjustifiable in any case in which operative measures of reasonable safety offer a possible hope of cure. A frank statement of the nature and severity of the reactions and the possibility of benefit should be made to the patient or to some responsible person before the treatment is instituted. This should be used in no case unless the tumor has been proven microscopically to be sarcoma. The percentage of apparent cures may be regarded as varying from 9.4 to 18.8. The author's study suggests that the toxins offer no expectation of benefit in cases of multiple melanotic growths, in cases of mixed cell growths, in cases with intraabdominal growths, and in cases with growths arising from subcutaneous tissue or bone, excepting, perhaps, giant cell growths. The Coley toxins may be legitimately tried in cases of single melanotic growths. They are apparently of value in cases of sarcomata arising in the nose and accessory sinuses, whether spindle-cell, giant-cell, or round-cell. The operative treatment of true giant-cell tumors gives in the majority of cases such good results that the toxins are not indicated. Their use is, however, warranted in those cases in which the growths are so situated that complete surgical eradication is impossible (such as giant-cell tumor of the spine) and in these cases the author believes that the attack should be primarily surgical, followed immediately by toxin treatment.

3. Easily Made Dialyzer for Abderhalden Test.—H. Greeley describes this device as follows: Take a small-sized test tube and file off the closed end, smooth the raw edge and fold over the cut end a piece of lens-

paper which should be held in place by a small rubber band twined over it about one-quarter of an inch above the edge of the tube. With a camel's-hair brush paint collodion over the outside of the lens-paper, dry it, and suspend the tube in one of larger size, upon whose lip the lip of the smaller tube should rest. Sterilize the apparatus in Arnold's sterilizer and apply the usual permeability tests. A little practice may be necessary before one learns to properly regulate the thickness of the coat of collodion applied.

3. The Value of Skimmed Milk and Its Dilutions in Fever.—L. Fischer believes that in pneumonia one should give no more than one-half of the quantity of milk formerly given. The frequency of feeding should also be reduced. Solid food should be prohibited during an acute febrile attack, regardless of the diagnosis, so that eggs, meat, vegetables, and bread should be prohibited. On the other hand gruels may be permitted in many diseases. Thus a farina or oatmeal gruel, or a barley gruel made with diluted milk is well borne and may be ordered. Fruit juices, such as orange juice and pineapple juice, are grateful and quench thirst. One of the best remedies to give is water for its antipyretic and laxative effects, and because it stimulates the kidneys. The tolerance for carbohydrates during fever is limited and in many cases they are contraindicated. Fat in the form of butter or cream is also contraindicated. Skimmed milk should be diluted with an equal quantity of water. By this method of feeding there is given a very low percentage of sugar and casein and practically no fat.

4. Effects of Caffeine and Nicotine on the Intestinal Musculature.—W. A. Frankland states that the effects of caffeine and nicotine on the activity of the intestinal muscles are important because a large number of patients with digestive disorders use coffee, tea, and tobacco. The effects of caffeine appear to be stimulating to the nerve centers from which come impulses to the intestinal muscles, causing contractions which are not coordinated for peristalsis. There does not seem to be any increase in the activity of the reflexes in the intestinal wall causing the peristaltic wave which would push the mass of intestinal contents downward. The tendency is to intensify contractions which narrow the lumen of the intestine and add resistance to the passage of its contents. On injecting nicotine in small doses into the jugular vein of dogs, Bayliss and Starling found that Auerbach's plexus was paralyzed by intense stimulation of the splanchnic nerves whose influence is not motor, but inhibitory. Under nicotine an intestinal contraction caused by pinching was not propagated in either direction. The rhythmical contractions become stronger, and as they pass in either direction do not perform the function of normal peristalsis. Cushny states that "nicotine produces nausea and vomiting with repeated evacuation of the bowels. Tetanic contractions of the whole intestine may occur with almost complete contraction of the lumen." Nicotine "first stimulates, then paralyzes the sympathetic ganglia" and stimulates the spinal reflex centers. In the light of these facts it is necessary to forbid the use of coffee, tea, and tobacco in the spastic stage of chronic constipation and in the conditions which result therefrom, as mucous colitis, mucous colic, and stercoral diarrhea. Coffee and tobacco taken at the same time unite their effects and form a combination opposed to rational therapeutic measures—an opposition too important to be neglected. Perhaps these articles are not often etiological factors without the assistance of other influences, but their evil effects are undoubted when the disease is once established.

6. Renal Functional Tests.—By J. T. Geraghty. (See MEDICAL RECORD, April 11, 1914, page 683.)

7. Pyloric and Duodenal Obstruction.—F. Buckmaster states that of the patients with gastric complaints each one must be studied individually and completely with the aid of a written history taking in all the details; complete physical examination in relation not only to the stomach but also to all other parts, as the cause of 90 per cent. of all stomach distress rests outside the stomach; associated with these the various test meals and special stomach and *x*-ray examinations should be made regularly. Clinically, pyloric or duodenal blockade begins to be important when gastric drainage is interfered with, just as is the case in blockade in the vesical neck. In either case with retention once initiated, fermentation and added infection result, and the condition progresses from bad to worse, in proportion to the amount of retention, as determined from time to time by the obstructing lesion. In both organs one may have an early muscular hypertrophy, with cramps and spasms of the outlet, and pains due to irritation and inflammation of the mucous linings; and in both, as the degree of obstruction increases, one will get motor insufficiency and dilatation, together with a sagging down of the base of the organ; and finally a complete inability to function. A correct diagnosis can be made in the early stage of these conditions of retention, before great damage has been done, and the proper treatment can be applied to the cause, which is better than to treat the one case indefinitely for chronic gastritis, and the other for chronic cystitis. A diagnosis of chronic gastritis, nervous dyspepsia and indigestion, hyperchlorhydria, hypersecretion, gastralgia, etc., in itself means nothing, and these should be dropped as diagnostic terms. It is wrong to wait for hemorrhage before one diagnoses ulcer; or for tumor, emaciation, cachexia, and coffee-ground vomit before making a diagnosis of cancer; or extreme emaciation, large dilated stomach, and daily vomiting before diagnosing pyloric blockade. Most cases of pyloric and duodenal obstruction are clinically curable. The doomed malignant ones may receive much relief by gastric drainage, hence early diagnosis and proper treatment in these cases is a very important matter to the sufferer. Likewise more attention should be given to the timely treatment of the causative conditions.

10. Cerebrospinal Examintaions in "Cured" Syphilis.—B. C. Corbus points out that too little attention is still paid to the diagnosis of syphilis at the time of the presence of the primary lesion. A great majority of physicians fail to realize the golden opportunity that an early diagnosis presents. Control of the treatment by the biological examination of the blood serum must be supplemented by spinal fluid examinations. Intensive intravenous injections should always be tried first, in early cases, before intraspinal injections are resorted to. Based on clinical observation, there is a strong possibility of a specific spirochete for the nervous system.

12. The Sero-Enzyme Test for Syphilis.—F. W. Baeslack states that through the parenteral incorporation of foreign or changed protein into the organism one may observe the formation of enzymes in the blood of the body. The formation of these enzymes may be stimulated in the experiment at the will of the investigator, or it may take place in diseases of infectious origin, when the organisms themselves or the products of their action on the cells of the body, or both, are swept into the blood stream and there cause the development of the ferments which are capable of breaking up the complex foreign substances into their simpler non-specific component parts, which are either assimilated or thrown off. There is in syphilis a disease simulating many other conditions in which cell proliferation and destruction occur, so that the resorption of these broken-down foci by the blood will further stimulate the formation of enzymes against the protoplasm of the cells undergoing degeneration as the result of the presence of the *Treponema pallidum* in the body. The sero-enzyme test for syphilis, when carried out with syphilitic testicular tissue, is probably a specific reaction, since the somatic cells are highly specialized, presupposing a specific enzyme for their cleavage. Thus in the use of the gumma produced in rabbits by inoculation, one makes use of a substratum which, when free from contamination, is superior to tissue prepared from the tissue of syphilitic patients, which of necessity is contaminated and is likely to give rise to positive reaction in other conditions. The reaction is not applicable in cases in which cerebrospinal fluid is to be tested. The reaction is more specific than the Wassermann reaction, for it has always given a positive reaction with the serum of tabetics, while the Wassermann reaction in this condition is negative in about 40 per cent. of cases. The authors also point out nine cases of tuberculosis which gave a positive Wassermann reaction, although no sign of syphilis could be found in any of these patients. The specificity of the test is further shown in the eight cases giving a negative Wassermann reaction and a positive sero-enzyme test. The technique of the reaction demands cleanliness and careful control of shells, tissue, and serum and the carrying out of the ninhydrin reaction. The sero-enzyme test for syphilis represents, with the exceptions indicated, a true biological test for this disease.

14. Etiology of Phlyctenular Ophthalmia.—S. Theobald concludes that the evidence adduced in support of the doctrine that phlyctenular ophthalmia is a turebculous or pseudotuberculous lesion is far from convincing. The frequency with which the subjects of phlyctenulosis give a positive reaction to diagnostic tuberculin tests is of little significance in view of the fact that the same tests show a scarcely smaller percentage of positive reactions in healthy persons. There is excellent authority for the contention that "until some responsible observer has demonstrated the presence of the tubercle bacillus in an extended series of phlyctenules," or, at least, until it has been shown to be sometimes present, the assertion that the affection is in any sense tuberculous is without warrant. In the present state of knowledge of the etiology of phlyctenulosis, the employment of tuberculin as a therapeutic agent in this affection is unjustifiable, not only because the ill-considered use of tuberculin is capable of doing much harm, but also because the clinical evidence shows pretty clearly that, if it is not actually harmful, it surely is not helpful. Definite clinical signs of the existence of tuberculosis, apart from the ocular inflammation, may justify the administration of tuberculin, but even in such circumstances the effect on the eye could be only indirect. As phlyctenulosis is essentially a disease of childhood, and the typical cases occur, not in adult life, but in children, it is from the study of these cases that trustworthy conclusions as to the etiology of the affection are to be drawn. The study of these childhood cases shows, from the almost constant association of facial eczema with the ocular inflammation, that phlyctenular ophthalmia, as was formerly very generally held, is an ocular eczema, due, for the most part, like facial eczema, to intestinal intoxication, and that tuberculosis is seldom if ever an etiological factor.

3. Osteoarthritis of the Hip.—R. L. J. Llewellyn and A. B. Jones are convinced that careful physical examination suplemented by a discriminating analysis of the subjective symptoms will enable one to diagnose the oncoming of an osteoarthritis even prior to the formation of bony outgrowths. The early symptoms consist of pain (local and referred), tenderness of hip, alterations in attitude and gait, with limitation of mobility. Like tuberculous coxitis the pains of osteoarthritis in this joint may either be localized to the hip region or referred along one or all of the nerve trunks from which the articulation derives branches. Quite in the initial stages a feeling of pain, or rather of painful stiffness, is felt in the joint itself. Sensitiveness to palpation of the capsule of the hip is a very common sign, but needs careful examination for its detection. Referred pains at their onset are more often than not

dismissed as examples of pure sciatic or crural neuralgia, and regarded as of gouty and rheumatic nature the unhappy victim for years roams from spa to spa in search of relief. The chief peculiarity of these pains is not so much their intensity as the extraordinary length of the period they endure. Thus patients with well-marked malum coxæ always assert that they have not only for years, but for two or even three decades suffered with these pains. Almost invariably these subjects suffer at the same time with pain in the loins, which, of course, enhances the liability to confusion with sciatica—a condition so commonly associated with lumbago. In the initial stages no change in gait and attitude can be detected save in the temporary limping that follows the occasional incarceration of the enlarged synovial villi. But with their growth and the advancing involvement of the membrane the intra-articular irritation produced gives rise to spasm of the related muscle, and this to malposition through slight flexion of the hip-joint. Relative fixity of the joint is, of course, the sign of chief diagnostic importance, and even in the very earliest stages there is present some limitation in the arc of motion in the hip. The presence of flexion contracture is of prime value as an indication of the articular site of the affection, but there are always present also further restrictions of movement. The diagnosis of osteoarthritis of the hip in its terminal stages presents no difficulty, but unfortunately at this period in its life history treatment is of little avail.

British Medical Journal.

August 8, 1914.

1. Vis Medicatrix Naturæ. J. A. Thompson.
2. Antidysenteric Vaccination. W. Broughton-Alcock.

1. Vis Medicatrix Naturæ.—J. A. Thomson states that the healing power of Nature may refer to the extraordinary capacity that many living creatures have of healing their wounds and regrowing lost parts. Another very interesting aspect of the healing power of Nature is the way in which organisms defend themselves from injurious intruders, or parasites, or poisons. The title, Vis Medicatrix Naturæ, might also well enough apply to the part Nature plays in hygiene—a most alluring subject: how the sunlight is the most universal, economical, and effective destroyer of many disease germs; how various bacteria and infusorians make a clean thing out of an unclean, etc. The healing power of Nature might also refer to the fundamental healthfulness of wild Nature. The author conceives of the healing power of Nature as a means by which Nature ministers to the human mind all more or less diseased by the rush and racket of civilization, and helps to steady and enrich human lives. There are deeply rooted, old-established, far-reaching relations between man and Nature, which one cannot ignore without loss. It is a condition of sanity to know the country and the seasons, the hills and the sunrise, the birds and the flowers; to know—not merely to read about—the sting of the wind-driven snow and the changeful music of the sea. "There would be less 'psychopathology of everyday life' if we kept up our acquaintance with the bonnie briar bush and the cry of the whaup on the moorland." It is necessary to keep in touch with Nature in order to get the fundamental impressions of power, of largeness, of pervading order, of universal flux, of intricacy. The healing power of Nature is manifested thirdly in the beauty that is everywhere. Another healing virtue in Nature is to be found in the perennial interest and orderliness of Nature, which speaks to the moral as well as to the intellectual ear.

2. Antidysenteric Vaccination.—W. Broughton-Alcock, after recognizing from practical experience on man the impracticability of the employment of heated Shiga bacilli in subcutaneous injections in single or multiple doses, tried several other methods and at length arrived at a simple and practical one which may render service should the occasion for its use arise during the present war. Any race of *B. dysentericus* may, when treated, be so employed. The strains of all varieties of dysenteric bacilli at the Pasteur Institute show in man an extreme reaction, this being due to their endotoxicity, which is present in both recent and old laboratory strains, living and dead. The author's method consists in taking a twenty-two to twenty-four hours' culture of *B. dysentericus* on a test tube of peptone agar. This culture is washed in saline 0.9 per cent., and is centrifugalized. The deposit is diluted in 2 c.c. fresh saline and heated to 56° C. for one hour. The author counts or otherwise enumerates the bacilli per c.c., and places the 2 c.c. in 20 c.c. normal, heated, pooled (two or more) human serums for 10 c.c. normal heated horse serum. They remain together over night. If the author uses the former, he places the mixture in the ice house so that any possible spirochete may be destroyed. After well centrifuging twice (the second time after adding saline to wash the bacilli), the deposit is mixed with 0.9 per cent. saline, so that 1 c.c. contains 350,000,000 bacilli to the c.c. Preventive injections are made four at a time, and when possible in the afternoons; first dose, 1 c.c., that is, four injections of ¼ c.c. each made in the left side of the back over muscular tissue, and where the braces or kit to be carried by the soldier do not press (not in the arms). The skin is well raised and injections are made into the loose subcutaneous tissue. The second dose of 2 c.c. follows about eight or nine days later in similar fashion. A third similar dose may be made. The reactions most carefully followed have never in over 200 subjects been marked nor have they caused any inconvenience. The reduction in both local and general reactions to the untreated microorganism is really striking. All subjects the author has vaccinated live in endemic areas; so far there have been no cases among them. The above method is noted for its marked simplicity and for the rapidity with which a vaccine may be made—and used prophylactically and therapeutically—from the first pure culture of the particular microorganism that is causing an epidemic, despite the numerous varieties in any group.

Tongue Chewing.—B. Myers notes that this condition consists in the chewing of one side of the tongue by the teeth after practically the identical manner in which some children chew gum. In the process the premolars and molars of the particular side of the jaw move inward over the tongue for about a quarter of an inch, and then glide over until the upper and lower molars are in apposition again; then the movement is repeated. The rate is about ninety per minute. The chewing movement may be kept up for a few seconds or minutes, or for half an hour. It may be performed once or twice daily, or intermittently, at various intervals. The repetition of the habit makes part of that side of the tongue distinctly red, and occasionally inflamed and indented. Tongue-chewing is first noticed about the second year of life, and persists until middle age, or, perhaps, throughout life. It tends to be less noticeable with advancing years. Either sex may suffer from it. It occurs, apparently, in healthy families, in which certain members suffer from habit-spasms. Several members of one family may suffer from it. The habit is inherited, as far as one can see, and not copied. The same side of the tongue is always chewed in the same individual. The mental condition is quite normal, and the general health is not interfered with in any way. Bromides stop the tongue-chewing, but in time, after the patient leaves off the drug, the habit recommences.—*British Journal of Diseases of Children.*

Insurance Medicine.

Indigestion, a Forerunner of Diseases of the Cardiovascular and Renal Systems.—In the past few years all medical directors and insurance men have been very much interested in diseases of the cardiovascular and renal systems and their terminal results, especially apoplexy, myocardial degeneration, coronary sclerosis, and uremia following chronic nephritis. In spite of the care in selecting risks our mortality from the above diseases seems to be increasing. Dr. Fred M. Hodges, Assistant Medical Director Atlantic Life Insurance Company, Richmond, Va., says that he has for the last three or four years been very much interested in a certain class of cases that may be overlooked at the time of examination, although a few years later many of the ordinary methods of examination would exclude them from insurance. During this time in a personal examination of 2,000 cases he has noted about thirty cases which would seem to him to come under this class. Cases having no symptoms or history of syphilis, alcoholism, or organic disease of stomach, appendix, or gall-bladder, etc., were selected. These persons seem to complain of slight indigestion, some discomfort after meals, and constipation before any cardiovascular or renal changes are noted. The cases may be divided into two groups. In Group I are those giving a history of constipation, indigestion, etc., followed by cardiovascular and renal changes with elevated blood pressure. In Group II those with a history of constipation and indigestion followed by low blood pressure, marked indicanuria, and neurasthenic symptoms with very few or no cardiovascular or renal changes.

In order to show the development of cases in Group I this group has been divided into three stages, as follows: (1) Those where there was only a complaint of indigestion and constipation; (2) those where there was this complaint and where complete uranalysis and the sphygmomanometer would exclude them from standard insurance; (3) cases showing very little previous history except indigestion and constipation with well-marked cardiovascular and renal changes. From his study of these cases Hodges draws the following conclusions: (1) Indigestion and constipation may in a small percentage of cases be the only impairment and forerunner of disease of the cardiovascular and renal systems, and this is of especial significance where there is a family history of cardiovascular disease. (2) Home office uranalysis and the sphygmomanometer are usually the first methods of examination to exclude the cases later showing cardiovascular and renal changes. (3) Routine examinations for indican should be made in all cases of chronic constipation and indigestion and especially those showing low blood pressure readings. (4) Applicants about forty years of age and over, with heavy responsibilities and twenty per cent. or more over maximum weight, make up the majority of the cases of the first group. (5) Whatever may be determined to be the actual cause of indicanuria, from these cases it does not seem to be a prominent factor as a forerunner of cardiovascular and renal disease, but is found in a certain percentage of cases in association with low blood pressure. (6) This subject presents a very interesting and important field for further study, and we should direct our attention to scientific research in this direction.—Proceedings of the Fourth Mid-Year Meeting of the Medical Section of the American Life Convention, March, 1914.

Dangers Attending the New Treatment of Syphilis.—Dr. George Parker, Medical Director Peoria Life Insurance Company, Peoria, Ill., states that one of the many things that have occurred to him as he has watched the progress of salvarsan and neosalvarsan, is that both will prove distinctly harmful in a way: Physicians in small country towns are using both salvarsan and neosalvarsan, and it is from these towns of three or four thousand inhabitants that we get many of our insurance risks. From one to three injections are given to each patient. The remedy is neither given properly nor properly controlled in many cases. This produces a chaotic condition, because prior to the advent of these remedies, mercury and potassium iodide were being used in a manner more or less effective, which under the newer treatment does not seem to be the case. Another danger—the patient with active syphilis receives one injection of salvarsan, witnesses the rapid disappearance of all his symptoms, and goes away overjoyed. He does not realize the seriousness of his condition, and fails to return for treatment. This places him farther from cure than he would have been under the old method of treatment. The statement that first came out that one injection cures is still prevalent in some of the smaller towns, where men are not posted thoroughly in regard to the treatment of syphilis, and this is doing harm. One advantage, however, appears to be the result of the new treatment. Syphilitics receive an injection, and while they may return to their old habits of living, as a result of the injection of the salvarsan or neosalvarsan, they are no longer liable to spread the disease.—Medical Section of the American Life Convention, March, 1914.

Cancer as Cause of Death in Prussia.—Two tables of statistics bring this subject up to 1912, the mortality for ten years being represented. The remarkable increase shown is of course disputed by those who claim that the mortality is a fixed annual quantity and that the percentages are not adapted to facts. The steady increase of the past few years with the completed methods of investigation should do away with this sceptical attitude. One table gives the joint mortality which in the decade 1903-1912, inclusive, increased from 21,258 to 30,045. The increase is considerably less marked in males (9,678 to 13,587) than in females (11,580 to 16,458).

A table based on relation of mortality percentages to 10,000 living persons, shows that the combined figures rose from 5.98 in 1903 to 7.32 in 1912; the ratios for males corresponding were 5.52 to 6.69; for women 6.42 to 7.92.—*Blätter für Vertrauensärzte der Lebensversicherung*, May-June, 1914.

After-Results of Operation and Life Insurance.—At the meeting of the British Life Assurance Medical Officers' Association held on November 5, 1913, the after-results of operations in relation to life insurance was discussed. Dr. F. de Haviland Hall pointed out that from time to time life insurance medical officers were confronted with cases where gastrojejunostomy had been done for non-malignant diseases, presumably of the pylorus. He had accepted one or two cases, but with a considerable addition. Dr. Ogier Ward said that if six months after operation the patient had regained and kept up his weight and was otherwise well, one might safely take him.

Book Reviews.

DIE PROGNOSENSTELLUNG BEI DER LUNGENTUBERKULOSE, mit eingehender Berücksichtigung der physikalischen und serologischen Befunde und der therapeutischen Prognostik. Dr. D. O. KUTHY and Dr. A. WOLFF-EISNER. Price, paper, $4.50; cloth, $5.00. Berlin and Vienna: Urban & Schwarzenberg, 1914.

THIS volume of 572 pages is perhaps the largest work ever written on the prognosis of a single disease. The authors are both well known through their previous works on tuberculosis. Under the chapter on general prognosis of pulmonary phthisis, they speak of an anatomical cure, a definite cure, and an economical cure. Under anamnestic data which must always be taken into consideration before deciding on the prognosis, the authors consider the age of the patient, his occupation, his financial condition, his temperament and character, the inherited disposition, diseases in childhood, acquired predisposition, in women condition of menses, and the duration of the disease.

Concerning the age at which cures are most frequent, it is interesting to note that the ages of 16 to 20 are here given first. Then 20 to 30, 30 to 40, and 40 to 50. The authors base these observations on the results obtained in the Hanseatic Insurance Sanatoria. Turban is quoted as having observed the greatest number of lasting cures under the age of 15 (66 per cent.).

The second chapter deals with the prognostic value according to status præsens, and here are enumerated for consideration the general condition of the patient, the degree of pain he experiences, his sleep, and the amount of dyspnea. The objective symptoms which the authors consider of importance in the prognosis are the color and condition of skin, the endurance of the patient, his former and present weight, temperature and the degree of hyperhidrosis, character of cough hemoptysis, character, quality and quantity of sptum, number and virulence of the bacilli, mixed infection, the physical findings resulting from a careful examination of the lungs, the *x*-ray picture, condition of heart, blood, digestive organs, kidneys, and nervous system.

Quite considerable space is devoted to the value of the diazo reaction. After quoting many conflicting opinions, the authors come to the conclusion that the absence of the diazo reaction is a favorable sign. Intermittent diazo reaction, not quite as good and constant reaction, is a decidedly unfavorable sign. Most interesting, if not novel, are the authors' conclusions on the prognostic value of the tuberculin reactions. They certainly differ with the conclusions of other authorities. Thus, they say that one must not assume that the intensity of the reaction has anything to do with the extent of the lesion. On the contrary, the tuberculin reactions are often most intense in cases to be considered clinically as well as pathologically favorable and these reactions lose their intensity as the disease progresses toward a fatal termination.

The third chapter deals with the prognosis as a result of therapeutic intervention. Here it is gratifying to see the fact emphasized that in order to obtain a favorable prognosis with the aid of tuberculin therapy, we must give this culture product in doses small enough to avoid even slight reactions. The authors do not speak enthusiastically of the ultimate results from a cure obtained by the hygienic and dietetic treatment in sanatoria and come to the conclusion that only by a combination of a sanatorium and specific treatment can results worth the while be obtained.

A short chapter is devoted to the favorable prognosis resulting from successful artificial pneumothorax. All in all, the book is one of the best of its kind and should be in the hands of all teachers and students of tuberculosis.

ZUR PROGNOSE UND AETIOLOGIE DER KINDER-HYSTERIE. Von Dr. A. TOBIAS, in Bremen. Mit einem Vorwort von Prof. Dr. E. FEER, in Zurich. Price 3.50 marks. Berlin: S. Karger, 1913.

THIS interesting dissertation on the hysteria of childhood is based upon the abundant material of the Pediatric Clinic of Heidelberg. There are presented the histories of thirty cases which are classified as follows: I. Cases of genuine hysteria; A. Those that are cured during the period of childhood, including cases that result from emotional stresses, those that follow trauma, those that follow acute diseases, those that follow chronic diseases, and those of unknown origin. B. Cases that are cured after childhood has passed. C. Cases that are not permanently cured. II. Cases that are not pure hysteria, including cases of organic disease and cases of epilepsy. Some of the important conclusions reached by the author are that a definite prognosis in these cases is more favorable than in the cases of adult hysterics. Particularly favorable is the prognosis in children of sound mind. In those of psychopathic inheritance the prognosis is always doubtful. But education and environment may influence the future of these children to an important degree. In the female sex and at a later age the prognosis is less favorable. It is also the less favorable the longer the disease has existed and the more powerful the original exciting factor may have been.

CLINICAL EXAMINATION OF THE BLOOD AND ITS TECHNIQUE. A Manual for Students and Practitioners. By Professor A. PAPPENHEIM, Berlin. Translated and Adapted by R. DONALDSON, M.A., M.B., Ch.B., F.R.C.S. Ed., D.P.H., Pathologist, Royal Berks Hospital Reading. Price, $1.25 net. New York: William Wood & Company, 1914.

THE material in this book appeared first as a chapter in Carl Neuberg's "Handbuch der Ausscheidungen und Körperflüssigkeiten" and later as an independent volume in German. It is intended as a guide, merely, to the examination of the blood and deals with only what is absolutely essential and of first importance. Chapter one presents a method of staining a description of the cells found in the blood and a differential diagnosis of the most important blood changes. Chapter two considers hemocytometry and chapter three hemoglobinometry. The cell descriptions are, of course, in accord with Professor Pappenheim's well-known theories and are particularly clear and illuminating. He recommends the Bürker chamber for counting the cells and a rather complicated pipette for diluting the blood for this purpose. For the estimation of the hemoglobin he favors the Autenrieth-Koenigsberger Hemocolorimeter. Two plates have been taken from his "Atlas." It is an excellent book to give any one the essentials of blood pathology.

THE FUNDAMENTAL BASIS OF NUTRITION. By GRAHAM LUSK, Professor of Physiology, Cornell University Medical College, and Scientific Director of the Russell Sage Institute of Pathology. Price, 50 cents. New Haven: Yale University Press, 1914.

THIS lecture was delivered at the New York Academy of Medicine last November and is published in its present form "that educated people may be able to obtain a better understanding of the principles of nutrition than is to be derived from current popular writings." Professor Lusk is one of the highest, if not the highest, authority in the world on this subject and he has compressed into about fifty pages all the essential elements of this important department of both economics and physiology. It is condensed, necessarily, but is exceedingly clear and to the point. It would make salutary reading for the food and diet faddists and can be highly recommended to all both in and out of the medical profession.

THE SOURCE, CHEMISTRY, AND USE OF FOOD PRODUCTS. By E. H. S. BAILEY, Ph.D., Professor of Chemistry and Director, Chemical Laboratories, University of Kansas. Price, $1 60 net. Philadelphia: P. Blakiston's Son & Co., 1914.

IN this volume the general principles of food production, manufacture and preparation are treated in such a way that the reader may have a practical knowledge as to what constitutes a good food, and where it is obtained. The important foods and beverages are discussed as to their source, method of preparation for the market, methods of packing, preserving and shipping, their composition and nutrient and dietetic value and their use by people of different countries. In handling such an extensive field the matter is necessarily condensed to the essentials, yet the author has managed to include much of historical and general interest. The book really should be issued as a companion volume to the cook book and used as constantly for it is packed with valuable information for the housewife. We cannot agree with the statement (page 157) "that the rice leaves the blood acid and the potato alkaline" and it is probable that the author does not mean just that. The quantity of milk for the Babcock test is erroneously given as 15.6 c.c. The volume is well bound and printed, but the proofreading has been sadly neglected so that the text contains many obvious errors.

Society Reports.

AMERICAN GYNECOLOGICAL SOCIETY.

Thirty-ninth Annual Meeting, Held at Boston, May 19, 20, and 21, 1914.

THE PRESIDENT, DR. J. WHITRIDGE WILLIAMS, OF BALTIMORE, IN THE CHAIR.

Forward Fixation of the Cervix as a Predisposing Cause of Some Retrodeviations of the Uterus, and an Operation for Its Release.—Dr. EDWARD REYNOLDS of Boston stated that the supports of the uterus were largely muscular, with the exception of the forward attachments of the cervix. The shortness of the latter formed an essential element in the anteflexion of the cervix. Firm forward fixation of the cervix while the fundus was comparatively movable, created a predisposition to the retrodeviations. The release of the forward fixation of the cervix as a preliminary to the performance of the standard operations for the retrodeviations added greatly to their percentage of success. The author described in detail the operation he performed.

Dr. HERMAN J. BOLDT of New York City stated that for what was called anteflexion of the cervix by Dr. Reynolds, and he believed by all other writers, he had been accustomed to use the term retroversion of the cervix, considering the direction of the cervix from the position of the external opening. It was a condition which was always congenital unless caused by pelvic inflammation. Heretofore he had always looked upon the shortened and not infrequently indurated condition of the sacrouterine ligaments as being the main factor in causing this position of the cervix, and he had, on a number of occasions in the last twenty years, cut the shortened ligaments to overcome the backache of which many persons so afflicted complained, several times relieving this symptom by the surgical intervention. That the holding forward of the fundus was due to the action of the round ligaments was, in his opinion, questionable in the greater number of such instances. These ligaments were not taut, except when the bladder and the rectum were full. The condition was usually an association of anteflexion of the body of the uterus with a retroversion of the cervix, and unless there be an atrophy of the anterior cervicocorporal junction, probably as a result of long standing of the condition, we would find the tissue at this junction unyielding; indurated, if we might call it so, since it was impossible to straighten it permanently by manual or mechanical means. Hence the mechanical dysmenorrhea of which many patients frequently complained. The usually present shortened anterior vaginal wall was part of the congenital malformation and was, of course, an additional factor in causing the retroversion of the cervix. He had always regarded the shortened and thickened sacrouterine ligaments to be a low-grade inflammatory process, a parametritis posterior. Furthermore, when the condition was of long standing and more or less atrophy had taken place in the anterior part of the cervix at the flexion angle, due to long duration and not infrequently increased size of the body of the uterus, the organ could not straighten itself by any physiological factor brought to bear upon it. We might, indeed, see the uterus assume a position farther backward in the pelvis, thus constituting a retroposition, and then the intraabdominal pressure might cause a still more acute flexion angle.

Dr. HENRY T. BYFORD of Chicago said he had usually regarded this condition of forward fixation of the cervix with retroversion of the uterus very much as the rest of the members. He had in many cases separated the bladder from the uterus quite extensively through a transverse incision and had drawn the parts together from the side to the median line, but he had not done exactly the same operation as that described by Dr. Reynolds. He had operated with the idea that when he drew the connective tissue from the sides of the cervix as far back as he could, he was drawing the tissues taut, getting support in front of the cervix which would hold it back more, making lateral support, drawing from the connective tissue around the sides of the cervix, and in that way replacing the cervix backward by the support of the connective tissue to the side of the cervix, instead of releasing the cervix merely from the traction of the anterior abdominal wall.

Dr. I. S. STONE of Washington, D. C., said that it seemed to him Dr. Reynolds' suggestion had been more or less covered in effect if we remembered the Mackenrodt fixation operation for retroversion. That is, denudation and separation from the anterior vaginal wall, dropping forward of the body of the uterus and fixing the anterior vaginal wall would answer the same purpose and overcome permanently the retroversion.

Dr. J. WESLEY BOVEE of Washington, D. C., stated that about fifteen years ago he began doing this work. He received his inspiration and instruction from one of the editions of the work on gynecology by Dr. William H. Byford, in which he (Dr. Byford) stated that if the cervicovaginal junction was less than two and one-quarter inches from the pubic arch, it was abnormally short and should be remedied. Taking his instruction from that, he devised procedures, working on the lower ligaments of the uterus. He studied the subject carefully and found we had another characteristic in certain anomalies of development to deal with; that is, an abnormally high attachment of the uterosacral ligaments to the cervix and abnormally low attachment of the anterior wall of the vagina, so that he realized many of these cases needed to have the defects remedied, and he did this by severing the anterior wall from the cervix, attaching it to a higher point and severing the uterosacral ligaments from the cervix and attaching it to the lower point which changed the leverage of the anterior wall more from the junction of the cervix with the body, thus giving stronger posterior leverage on the posterior wall of the uterus. He did this procedure in two ways—one very much after the plan mentioned by Dr. Reynolds by detaching the anterior wall from the cervix and attaching it again higher, and the other by making a transverse incision and lengthening the anterior wall, except he added this modification: he did it with interrupted sutures, and he inserted a small amount of soft rubber on account of oozing into the opening between the cervix and the bladder, which was attached to a piece of gauze with suture, the gauze being placed in the vagina and the gauze, when removed, pulled the rabber drainage out. The uterosacral ligament operation was beneficial in those cases in which there was traction of the uterosacral ligaments from inflammation, such as Dr. Boldt called posterior parametritis.

Dr. JAMES R. GOODALL of Montreal stated that after listening to Dr. Reynolds' paper it struck him that two classes of cases were being placed in one category; that the type of acute anteflexion of the uterus and the type of retroflexion were two distinct types which could not be considered as belonging to one class. For instance, if we took young girls who complained of severe dysmenorrhea, we would find associated conditions of the vagina and pelvis. Associated with an acute anteflexion of the uterus there was a short anterior lip of the cervix and a long posterior lip. This type of uterus when removed from the body and held by the cervix could not be undone. The anterior uterine wall was very fibrous in part and it was a type of uterus which in his experience, seldom if ever, became retroverted or retroflexed. That type of girl was big, muscular, whose physical development had gone on to an advanced stage, but the pelvic organs had remained somewhat infantile. In the other type of cases in which retroversion and retroflexion took place there was a lack of tone and a tendency to enteroptosis even before pregnancy had taken place, and with that type of uterus the fundus could be flopped about in very few hours after death. In one type of case, with acute anteflexion, the cervix was drawn into the hollow of the sacrum; in the other type of case, we did not get a long cervix, such as we expected to find in a case of acute anteflexion. These were absolutely two different types of cases which should not come in the same class, for in the one class we had tautness of the uterosacral ligaments, while in the other there was a laxity of everything and marked elongation of the uterosacral ligaments.

Dr. REYNOLDS, in closing, and in reply to the remarks of Dr. Goodall, stated that there was a distinction between these two classes of retroverted and anteflexed uteri. Retroversion seldom occurred in the class in which the anterior wall at the angle of flexion was hard and firm, and when he began to work with Dudley's operation he was doubtful whether the anteflexion could be corrected for any purpose in that class of cervix. Where we thought the cervix was the cause of the mechanical dysmenorrhea, release of the anterior fixation and posterior discission would straighten the

An Internal Alexander Operation.—Dr. HENRY T. BYFORD of Chicago considered the Alexander opera-

tion the most satisfactory for replaceable retroversion due to relaxation of the pelvic tissues. If lacerations about the vaginal entrance were present, they were also repaired. Operations upon the uterosacral ligaments were not advocated in ordinary cases because, according to the experience of the author, these ligaments would gradually grow shorter after an Alexander operation, if a small-sized pessary was worn for a few months to protect them from overstretching. When a median abdominal incision had to be made for pelvic conditions the ligaments were shortened through the incision in such a way that they drew toward the internal inguinal ring, as in the Alexander operation, and in such a way that the sutures were extraperitoneal. A fold was taken in each ligament and sutured. These folds were drawn through a peritoneal puncture near the internal ring and attached along the inner surface of the abdominal wall at this point, but extraperitoneally. This was easily accomplished by separating the peritoneum from the abdominal wall on either side as far as the internal ring.

The Effect of Laparotomy upon the Circulation.—Dr. W. D. GATCH of Indianapolis stated that the anatomical arrangement of the abdominal vessels presented three points of special significance. (1) The circulation through the abdominal viscera was through two sets of capillaries, separated by the portal vein and its radicles. This must slow down the rate of the circulation through the abdominal organs. It was well known that the pressure in the vessels of the liver was very low. (2) The veins of the abdomen had walls so thin that they were easily compressed by the slightest pressure upon them. (3) None of the abdominal veins had valves. In a series of experiments carried out on dogs he took simultaneous tracings of the intrathoracic pressure, of the intraabdominal pressure, of the pressure in the inferior vena cava, and of the general blood pressure. The pressure in the vena cava was taken by thrusting a cannula up through an opening in the femoral vein. He raised the intraabdominal pressure by injecting warm salt solution into the peritoneal cavity. The tracings showed that the intraabdominal pressure and the pressure in the inferior vena cava were always equal and rose and fell together. When the intraabdominal pressure was elevated until it was higher than the blood pressure, the circulation through the abdomen was abolished, the abdominal viscera being found bloodless at autopsy. What was the explanation of these findings? Suppose that the intraabdominal pressure be increased above the venous pressure, the veins would be compressed and no blood would flow through them until enough blood had been forced into them from the arteries to raise the intravenous pressure to the level of the intraabdominal pressure. Experiments had driven him to the conclusion that the chief and essential course which propelled the blood through the abdominal organs was the beat of the heart. The well-known fact that pressure upon the abdomen increased the output from the inferior vena cava was not evidence against this view, because such increase was not maintained unless the circulation was greatly depressed. The absence of valves in the abdominal veins prevented any variations in intraabdominal pressure due to movements of the abdominal walls from pumping the blood toward the thorax with any degree of efficiency, because as soon as the pressure was released there was a regurgitation. That the heart alone was capable of keeping up the abdominal circulation was proved by the experiment described. The effect of anesthesia so deep as to abolish completely the tone of the abdominal wall was to promote the accumulation of blood in the abdomen and limbs, and in his opinion not uncommonly caused a failure of the circulation during and after operation. It was fortunate that laparotomy was nearly always performed with the patient either in the horizontal or in the Trendelenburg position, for if it were usually done with the patient deeply anesthetized and in the feet-down posture many more fatalities would occur. Operations both on animals and on man were much better borne under an anesthesia so light as to preserve the tone of the muscles. This was the reason why there was much less so-called shock under nitrous oxide oxygen anesthesia than under anesthesia due to more powerful agents. In performing exploratory laparotomy which he had recently done for gunshot wounds of the abdomen, he had several times noted on opening the abdomen what he felt certain was a great increase in the hemorrhage from a severed intraabdominal vein. In one case in which the bullet wounded the vena cava there was but little blood found when the abdomen was first opened, but when he raised the transverse colon a frightful gush of blood took place. He had made similar observations in two cases of gunshot wounds of the liver.

Some Experiments Defining the Dangers of Anesthesia.—Dr. YANDELL HENDERSON of New Haven said the time was close at hand when in every well ordered and scientific operating room, where ether was used at all, instead of it being poured as a liquid over the patient's face and into his mouth, there would be a device, and it could be a very simple device, on a stand at the elbow of the anesthetist, or over in the corner, or possibly even down in the basement, in which the ether would be volatilized, and from which it would be conducted to the patient's nose and mouth as if it were merely an unusually strong variety of nitrous oxide. That this idea was rapidly gaining recognition and acceptance was evidenced by the insufflation method of Meltzer, the simple and accurate device of the speaker's colleague, Dr. J. M. Flint, and most recently by the anesthetometer of Connell. It was at once a simpler, safer, and more scientific procedure to administer the gas which we called ether vapor than it was to handle liquid ether. Insufficient breathing was an extremely common consequence of etherization. It added to evil influences of a more or less prolonged period of insufficient oxygen supply to the other conditions lowering the patient's vitality. It was clear that the logical procedure to prevent this was some method of administering ether vapor such as Dr. Gatch showed to be so advantageous as nitrous oxide and also some method of administering a sufficient amount of CO_2 in the air breathed after the anesthesia was ended to stimulate respiration to a more rapid elimination of the ether with which the body was saturated, and to prevent apnea or subnormal breathing, anoxemia and cyanosis.

Nerve Blocking.—Dr. M. L. HARRIS of Chicago stated that while experiments showed that novocain was only about one-seventh as toxic as cocaine, it should not be forgotten that serious and even fatal results might follow an overdose. The amount of novocain that could be injected without producing toxic symptoms varied considerably and depended largely upon the rapidity of absorption. If a plain watery solution was used and injected in the region where absorption was rapid 0.3 gm.—0.4 gm. might produce symptoms, but if the solution be one which absorbed slowly 0.5 gm.—1.0 gm. might be used without danger. The more rapid the absorption, the less marked the anesthesia, for it required a certain length of time for the drug to act. The addition of adrenalin to the solution materially increased the degree and duration of the anesthesia. Hoffmann had found that the addition of ¼ of one per cent. to 1 per cent. of potassium sulphate also materially increased the duration of the anesthesia, and that he was able to produce anesthesia with a much weaker solution. The speaker had found in his own work that by the addition of calcium chloride in varying strengths, the anesthesia might be prolonged for two or three hours without difficulty, and that a weaker solution might be used than without the calcium chloride. The formula which he was using at present and which had given him the best results was novocain, ¼ to 1 per cent., calcium chloride, ¼ to ½ of 1 per cent., chlorbutanol 0.8 of 1 per cent. in distilled water, to which were added four to five drops of the 1-1000 adrenalin solution to 30 c.c. of the mixture. It was very essential that the mixture be properly prepared and the method he used was the following: The distilled water was sterilized by boiling. The novocain was then added and the boiling continued not to exceed two or three minutes, as prolonged boiling spoiled cocaine. When this had cooled down to below 150° F. 1.0 gr. of chlorbutanol was added to every 100 c.c. of the novocain solution. Water dissolved only about 0.8 of 1 per cent. of chlorbutanol, but 1 per cent. was added merely as an easy way of insuring a saturated solution. The undissolved part simply settled at the bottom. A 2 to 4 per cent. solution of calcium chloride in distilled water was made and sterilized, and then the chlorbutanol added the same as to the novocain solution. The solutions were kept separately and mixed just before using. In this way the percentage of the ingredients might be quickly varied to suit the particular case. The adrenalin should never be added until just before using, as it was very unstable and soon spoiled if left standing in the solution, which was indicated by the solution gradually turning a reddish color. The adrenalin solution

should be comparatively fresh and if it had turned reddish in color it should not be used. The chlorbutanol was added because it had distinct anethetizing properties of its own, and being soluble in lipoids increased the anethetizing effect of the novocain. As to the advantages of nerve blocking, it was less dangerous. It would be admitted that practically all substances used for this purpose were more or less toxic, but the degree of toxicity was comparatively well known, and as the substances were injected locally to affect nerve trunks and not used generally to affect nerve centers, it was easier to guard against an overdose. The method was devoid of dangerous and unpleasant complications which so frequently followed the use of general anesthesia or anesthetics, particularly ether and chloroform. In his experience the great majority of patients preferred being conscious and looked upon the loss of consciousness as one of the greatest drawbacks to an operation. The psychic elements in these cases had been greatly overestimated. The horror of an operation was based on, first, the fear of pain; second, the loss of consciousness, and, third, apprehension as to the outcome. He had done under nerve blocking 234 operations on 217 patients, and in his paper he presented a list of cases showing the wide applicability of the method. The number of failures was six, and the number of deaths was seven.

Spinal Anesthesia in Gynecology.—Dr. GEORGE GELLHORN of St. Louis, Mo., pointed out that the severity of an operation stood in direct proportion to the amount of ether inhaled. The popular ether drop method was not as safe a procedure as would appear from existing statistics. The latter were incomplete in regard to the number of fatalities and did not take into consideration late complications which might either lead to death or seriously interfere with convalesence. There should not be any one routine method, but the needs of the individual case must govern the choice of the mode of anesthesia. In gynecological work, spinal anesthesia offered particular advantages and showed most impressive results. The mortality rate from spinal anesthesia could not be determined by statistics. These were unreliable. The majority of deaths occurred during the experimental stages of the method. The anesthetic itself seemed to have nothing to do with the mortality. Stovain, tropococain, and novocain were more or less equivalent. His experience was limited to the last named drug. The safety of spinal anesthesia depended upon first its accurate technic, and the strictest observance of even the minutest detail was of paramount importance. Reports of deaths, therefore, must contain all details of the technic employed before they could be admitted to serious consideration. It had been proven in thousands of cases that by painstaking technic, not only death but collapse and other alarming complications of earlier days could successfully be avoided. Contrary to popular prejudice, there was no psychic trauma connected with spinal anesthesia. Nausea and vomiting during operation were reduced to a minimum or altogether absent. The abdominal walls were fully relaxed, and the intestines remained quietly within the peritoneal cavity. Therefore, all operative manipulations were rendered easier, and the brusque handling of the viscera was obviated. All this tended to lessen the operative shock, and as nerve impulses did not touch the brain, spinal anesthesia was the ideal measure of anoci-association. In a certain small percentage analgesia was incomplete, then a few whiffs of ether sufficed to render the operation painless. In a list of 127 abdominal and 42 vaginal operations he showed that every kind of gynecological operation, not including those on the kidney, could be performed under spinal anesthesia. There had been no death from this method. In all four patients died, two of these from sepsis after radical operations for cancer of the cervix. The post-operative care of spinal cases was strikingly easy. The usual post-operative symptoms appeared in greatly mitigated form, or were altogether absent. Patients who had had personal experience with ether and spinal anesthesia declared themselves in favor of the latter. An annoying and comparatively frequent by-effect was headache, which, however, yielded spontaneously or to bromides, and constituted no danger to the patient. Other by-effects, such as backache, paresthesias, and temporary paralysis, seemed to have become less frequent with improvements in technic, and it was the consensus of all observers that lasting ill effects were conspicuously absent. Spinal anesthesia markedly lessened the blood pressure and should therefore be used with caution in cases of pronounced hypotension. Acetonuria occurred after spinal anesthesia, as well as after inhalation narcosis, but exerted no deleterious effect upon the patient; it disappeared spontaneously about five days after operation. Spinal anesthesia enabled us to operate with safety on patients in whom ether would be contraindicated. It was thus chiefly applicable in cases where the seriousness of the affection, the magnitude of the operation, or coexisting complications (cardiac and pulmonary lesions, nephritis, diabetes, hyperthyroidism, advanced age, debility) constituted a particular risk. Minor operations should be reserved for ether narcosis. Spinal anesthesia was contraindicated in kyphoscoliosis and other marked anomalies of the spinal column, diseases of the central nervous system, profound shock, or marked hypotension from other causes; sepsis, and fevers of unknown origin; furthermore, in neuropathic individuals and where there was a strong prejudice against the method. Suppurations and eruptions near the desired site of injection forbade the use of spinal anesthesia until aseptic conditions could be established.

Dr. FREEMAN ALLEN, of Boston, said that while he was not an ardent advocate of spinal anesthesia in certain cases, yet as a professional anesthetist he felt called upon to defend ether. He felt that a great deal of the condemnation that ether had been receiving lately was due to the fact that surgeons and patients had been the victims of unskillful administration of ether. He thought that surgeons were much too apt to put up with administrations of ether by persons who were comparatively unskillful and then to blame ether anesthesia in general. If he were a surgeon and lived in a community where the services of a really skilled anesthetist were not obtainable, he should certainly use spinal anesthesia very largely, if not exclusively. He agreed with Dr. Gellhorn that there was no psychic shock whatever when a patient had been properly prepared for spinal anesthesia and was properly handled during the same.

Dr. JOHN O. POLAK of Brooklyn, New York, had had two cases of very prompt and aggravated shock coming on from the immediate use of the Fowler position after abdominal operations for general peritonitis where a stab wound incision was made and drainage instituted. It had been their custom to have these patients placed in a horizontal position or moderate Trendelenburg position for the first few hours. They got those two cases up in the Fowler position and in coming out of the anesthesia both were in the most severe shock as the result of it, and only by change of posture was the shock relieved. In regard to spinal anesthesia, during the last two years they had used it in a number of cardiac cases, in cases of tuberculosis and diabetes, and in those in which they had to do obstetrical or gynecological operations. In those extremely severe cardiac cases that complicated pregnancy the use of spinal anesthesia had brought to them a new era of obstetric surgery.

Dr. SETH C. GORDON, of Portland, Me., had given ether and chloroform for over 50 years, and had never seen but one death from chloroform. He had never seen but one death which in his opinion was traceable to ether. He believed that the main trouble had been in the administration of those two anesthetics, and that the more experience we had and the more we adopted modern methods, as for instance, the drop method of ether, we had something that was certain in any case where we were obliged to resort to a surgical operation.

Dr. M. L. HARRIS, of Chicago, found under nerve blocking there had been no deaths, so it was perfectly safe from that standpoint. He had had occasion to operate on a number of patients who had undergone previous operations under general anesthesia, and without a single exception the patients had expressed themselves as infinitely preferring nerve blocking and would never think of taking a general anesthetic again. Until we found some way of limiting spinal anesthesia to a distinct level or to a certain part of the cord, he thought peripheral anesthesia or nerve blocking might have certain advantages over intraspinal anesthesia.

Dr. GEORGE GELLHORN, of St. Louis, Missouri, said he had never done anything but gynecological operations under spinal anesthesia, but was certain that in operations upon the extremities nerve blocking would be the method of anesthesia of the future.

Ultimate Results of Surgical Intervention in Simple Cholelithiasis.—Dr. JOHN G. CLARK of Philadelphia stated that in his review of 160 cases of cholelithiasis he emphasized the fact that modern surgery had en-

tirely recast the clinical history of cases of cholelithiasis, and that in the newer interpretation symptoms which were formerly considered as essential for the establishment of a diagnosis of cholelithiasis were now looked upon as terminal rather than initial indications of biliary defects. In one group he had included cases in which there was an operation for cholelithiasis without any associated gynecological conditions. In the second group were found all of the cases in which gallstones were discovered in association with gynecological or other abdominal operations. In only 14 per cent. of his series of 160 cases had he failed to secure accurate notes as to the outcome. In this list, no case had been included which had been operated upon under nine months. It was to the ultimate recovery that he had particularly directed his attention in this study of cases. In all cases where there was nausea after twenty-four hours, he attached a saline reservoir to the drainage tube and under one foot of hydraulic pressure permitted the fluid to drop slowly into the gall-bladder. Great care was observed to avoid the slightest excess of pressure which might induce a rupture about the point of insertion of the tube in the gall-bladder. The drainage in this series had usually been maintained for ten days. This rule was an arbitrary one and in some cases the length of the drainage period might be extended. Within the last two years he had turned towards cholecystectomy in a greater proportion of cases, for experience had shown that if the wall of the gall-bladder was thick and indurated, or if it was dilated and very thin, or if, on inspection of the interior of the organ, the mucosa was eroded or showed a strawberry mottling, he performed cholecystectomy. Occasionally he had closed the gall-bladder without drainage after the removal of uncomplicated gall-stones, but he preferred to use a simple drain for fear of the rupture of the gall-bladder and escape of bile into the peritoneal cavity was thus avoided. From this series of cases he concluded that (1) simple drainage was sufficient in all cases of cholelithiasis where there was no symptom attributable to their presence. (2) When the gall-bladder was thickened, greatly dilated, or was the seat of the so-called strawberry change as described by Moynihan, cholecystectomy was preferable. So-called gastralgia, indigestion and dyspepsia he would place in heavy type and let it stand out so boldly that it would serve as a target to be immediately demolished. In gynecological cases with coincident symptoms in the upper abdomen, the gall-bladder was by far more frequently the seat of disease than any other organ. In a vastly larger series of gynecological cases, gastric or duodenal ulcers, or cancer of the stomach, had been so infrequently found as to be almost negligible. In estimating the immediate and remote results of these combined operations he had arranged his cases under three separate headings: First, simple gall-bladder cases, in which the surgical treatment was directed to the relief of cholelithiasis; second, the cases in which some pelvic operation was performed and gall-stones, not producing symptoms, were discovered, and, third, gynecological cases in which there were unmistakeable symptoms of associated gall-bladder disturbance. So far as immediate mortality was concerned, the first group consisting of 51 cases was attended by 6.1 per cent. immediate mortality, the second by 4.3 per cent., and in the third there was no fatality. Of six fatalities in his series of cases, four of the cases died from destructive results of advanced cholelithiasis. In only two could death be attributed to any defect in operative technique. In one there was a leakage with the formation of a subphrenic abscess; in the other, a peritonitis. These two deaths might have been avoidable. In none of the combined operations where there were no symptoms attributable to gall-stones was there a fatality.

Dr. Reuben Peterson of Ann Arbor, found in about one thousand abdominal sections that there were gall-stones present in about 12 or 14 per cent. This included his own private cases as well as the University Hospital cases. He had adopted the one operation of simply removing the gallstones and draining. He had not removed the gall-bladder in any case. He had found quite a percentage of cases where he did not think it was advisable to perform any operation upon the gall-bladder. He had found an unusually large proportion of cases of cancer that had gallstones. In the pus cases he had refrained from operating on the gall-bladder.

Dr. Philander A. Harris of Paterson, N. J., had not often removed gallstones from patients when operating upon them for gynecological troubles. He did not think he had removed the gallstones in more than half a dozen cases. He did not believe he had found gall-stones in more than four or five per cent. of the cases he had palpated through the abdominal incision, so that his experience did not correspond with that of Dr. Peterson. He had removed the gall-bladder in at least 70 per cent. of the cases on which he had operated, something less than 200. Removal of the gall-bladder was good practice.

The New Efficiency Systems and Their Bearing on Gynecological Diagnosis.—Dr. Robert L. Dickinson of Brooklyn, New York, said that many of the methods of Taylor's "Scientific Management" of factories were adaptable to office, dispensary, and hospital group diagnosis. He gave an outline suggesting how responsibilities might be recast and grouped by function; how all processes might be standardized, then reduced to writing, instruction carried on, and then constant inspection to check up every one's results, while studies of time and waste motion in the operating room and ward were undertaken. Attention was drawn to the need of systematic study of fatigue among nurses, as had been done in other occupations. Reference was made to co-operative methods, as instanced in the Associated Out-Patient Clinics of New Cork; of the Hospital Efficiency Committee of the Philadelphia County Medical Society, representing fifty-five hospitals; of the great new Mayo building just opened, and in associations of groups in cities. Some examples of printed forms were submitted, such as a full preliminary history to be made out by the patient herself, and also printed directions to gynecological and pregnant patients.

Hospital Efficiency with Particular Reference to Product Rather than Expenditure.—Dr. E. A. Codman of Boston, stated that at present trustees of hospitals gave attention to the efficiency of their institutions in expenditures, but they had made little or no effort to find whether the treatment of the patients which was given by their medical and surgical staffs was good or bad. It had been taken for granted that the public preferred to be treated by a physician or surgeon who had a great reputation, even if he was hurried or careless, than by an individual or lesser reputation who could afford the time and pains necessary to obtain a good result in the treatment of disease which afflicted the patient. Hospitals in which promotion was made by a seniority system could not help tending to the inevitable practice of allowing the more capable surgeons to do the easier and more brilliant cases, while the more tedious and difficult and grave cases might be referred to the younger men whose private reputations made little demand upon their time. There seemed to be some ground for the contention that it would be better to have a young surgeon do a large number of easy operations, so that when he was older his experience might benefit the more difficult cases which fortunately were much fewer in number. Dr. Codman pointed out the value of the "End Result System," and said it tended to bring this change about.

A Critical Review of 500 Published and Unpublished Cases of Abdominal Cesarean Section for Eclampsia.—Dr. Reuben Peterson, Ann Arbor, Mich., read a paper on this subject, in which he presented the following summary and conclusions: (1) Since the 500 cases of abdominal cesarean represent the work of 259 operators they are a very fair index to the present status of the operation as a method of treating antepartum eclampsia. (2) Since the results of operative obstetrics, especially abdominal section, are far better at the present time than formerly the value of the operation as a method of treatment of eclampsia can only be judged by grouping the cases chronologically. (3) Between 1903 and 1913 there were 283 cases of eclampsia treated by abdominal cesarean section, with 73 deaths, or a maternal mortality of 25.79 per cent. Up to 1908 there were 198 cases, with 95 deaths, or a mortality of 47.97 per cent. Hence the maternal mortality in the five-year period has been reduced nearly one-half. (4) Hence the old figures of a 40 or 50 per cent. maternal mortality from abdominal cesarean section for eclampsia are incorrect and should no longer be quoted. (5) The mortality percentage quoted above (25.79) can be considerably lowered by care in technique and by not making use of the suprapubic route when there is great probability that the woman has been infected from below. (6) Nearly one-fifth of the entire series, 91 operations, were performed by thirteen men having five or more cases to their credit, with 17 deaths, or a maternal mortality of 18.68 per cent. (7) Deducting 15 cases

where the proportion of moribund and septic patients was very high, the remaining 76 cases, with 10 deaths, give a maternal mortality of 13.15 per cent. (8) Although an eclamptic may die after a single or survive after many convulsions, the latter must be utilized as an indication of the degree of eclamptic poisoning until we have a better method of estimating the patient's condition. (9) Emptying of the uterus either spontaneously or by artificial means, while it puts a stop to the further elaboration of toxins from the fetus, the placenta or both may not be sufficient to prevent further convulsions or in certain cases death of the mother from intoxication. (10) In the present series convulsions were caused after abdominal cesarean section in 251 out of 457 cases, or in 54.92 per cent. These statistics agree with those made up from those obtained from thousands of cases of eclampsia showing that convulsions cease after emptying of the uterus either spontaneously or artificially in from 52 to 62 per cent. of the cases. (11) Even when the convulsions cease after delivery a certain proportion of the patients die. In 146 cases where the convulsions ceased after abdominal cesarean section during the five year period (1908-1913) there were 41 deaths or a maternal mortality of 19.8 per cent. (12) While the above percentage of patients died after emptying the uterus by abdominal cesarean section after cessation of the convulsions the mortality is much less than where the convulsions continue, since in 130 of such cases there were 41 deaths, or a maternal mortality of 31.53 per cent. (13) The operative treatment of eclampsia has never been given a fair trial. To do this the uterus should be emptied quickly, as soon as possible after the onset of the first convulsion, not emptied after all kinds of medicinal treatment have been tried and failed. (14) In the present series there were 25 deaths after 124 operations performed after one to five convulsions, or a maternal mortality of 20.32 per cent. (15) The best results in the operative treatment of eclampsia are bound to follow immediate emptying of the uterus in cases where the woman has not been infected by frequent vaginal examinations or attempts at delivery from below. This is shown by the following: (16) In 60 of the 124 cases where the operations were performed after from one to five convulsions, where no or only one or two vaginal examinations had been made and where no attempts were made to deliver from below, there were only 9 deaths, or a maternal mortality of 15 per cent. (17) The increase in mortality due to delay is shown by a mortality of 30.33 per cent. where the operations were performed after the sixth convulsion. This is 10 per cent. higher than after quick delivery and 5 per cent. higher than the total mortality resulting during the same period (1908-1913). (18) In 60 cases where the convulsions ceased after operations performed after from one to five convulsions there were 8 deaths or a maternal mortality of 13.33 per cent. The mortality is twice as high (26.92 per cent.) after operations performed under the same conditions except that the convulsions continued. (19) When the abdominal cesarean sections were performed after more than five convulsions there was a resulting mortality of 26.31 per cent., where there was a cessation of the convulsions, and 36.36 per cent. where they continued. (20) The average number of convulsions in 386 cases of eclampsia in the abdominal cesarean series was 9 where the cases were not grouped. The average was 10 up to 1908 and 8 from 1908-1913. (21) Twins occurred 31 times in 500 cases of abdominal cesarean section for eclampsia, or in 4.02 per cent. of the cases. This is over three times as frequent as are twins in normal cases. (22) Excluding premature children and counting as living all children who survived one hour after delivery, there were 9 deaths from 1908 to 1913 where 248 children were delivered by abdominal cesarean section, or a fetal mortality of 3.62 per cent. Under the same conditions fetal mortality was 10.69 per cent. if children dying the first three days after delivery were counted among the deaths. Even estimating the fetal mortality by this method it is much better than by any other method of treating eclampsia. (23) The fetus as well as the mother is affected by eclamptic poison. The greater the number of the eclamptic convulsions before delivery the greater the fetal mortality. Hence, for the sake of the fetus, the uterus should be emptied as soon as possible after the first convulsion. If other factors in the case call for abdominal cesarean section the chances of the fetus will be much better than if another method of delivery be employed. (24) In 474 cases of eclampsia in the present series, 83.75 per cent. were primiparæ and 16.17 per cent. multiparæ. The relatively larger proportion of primiparæ was due to the fact that primiparous conditions, such as undilated and rigid cervix and rigidity of the soft parts more often called for the abdominal operation than for other methods of delivery. (25) The maternal mortality is higher after abdominal cesarean section in multiparous women than in the case with primiparous eclamptics. In the present series in 225 primiparæ the maternal mortality was 24.44 per cent., while in 48 multiparæ the mortality was 27.08 per cent. (26) The fetal as well as the maternal mortality is higher in multiparæ after abdominal cesarean section. This is probably due to the greater degree of intoxication among the multiparæ, since in both primiparæ and multiparæ the children, because of the nature of the operation employed, escape the traumatisms of labor. The greater intoxication among the multiparæ is probably due to their being on the average older than the primiparæ, the average of the former in 77 cases being 32.6 years, while the average age of the latter in 397 cases was 24.6 years. (27) The maternal mortality in eclampsia after abdominal cesarean section steadily increases with the age of the patients, it being 23.63 per cent. between the ages of 16 and 20, and 31.11 per cent. between the ages of 31 and 35. (28) The number of eclamptic cases in the present series steadily increased from the fifth month of gestation up to full term, also the farther advanced the pregnancy the lower the maternal mortality. (29) Unless the aseptic technique employed in attempts to deliver from below be known, abdominal cesarean section is contraindictated, so great are the dangers of fatal peritonitis when the patient is infected. (30) The high death rate of abdominal cesarean section after operative procedures is shown by the fact that there were 10 deaths in 29 such cases, or a maternal mortality of 34.48 per cent. This 9 per cent. increase in mortality over the total mortality (25.79 per cent.) during the same period was undoubtedly due to sepsis, shock and delay in emptying the uterus. (31) The mortality is distinctly higher after abdominal cesarean section in eclampsia if vaginal examinations have been made prior to the operations. The danger increases directly with the number of examinations made and the lack of asepsis employed. (32) Any obstetric condition which makes delivery by the natural passages prolonged and difficult, may be an indication for abdominal cesarean section in eclampsia. If delivery be decided upon the uterus should be emptied by the method which will perform the work the quickest and with the least trauma and shock to mother and child. However, it must be borne in mind that there is more danger of sepsis when the peritoneal cavity is opened. (33) With the present state of our knowledge of this operation for eclampsia it cannot be denied that older and more tried methods of emptying the uterus in eclampsia give better results in eclamptics with normal pelves and soft parts, hence should not be lightly discarded in favor of the more brilliant and more easily performed abdominal operation. (34) But with a maternal mortality after abdominal cesarean section of 18.68 per cent. in 191 cases of eclampsia in one series, 13.13 per cent. in 76 cases in another, and 15 per cent. in 60 cases where the uterus was emptied after a few convulsions, the operation under consideration has reached a stage where it can no longer be disregarded by obstetricians who have based their opposition to the procedure upon statistics which were altogether too high.

Mechanics Involved in the Cause and Surgical Relief of Downward and Backward Displacement of the Uterus.—Dr. Geo. H. Noble, of Atlanta, Georgia, spoke of the measurement of intraabdominal pressure in the abdomen and vagina of normal subjects and compared the same with the tests made in cases of cystocele, rectocele and procidentia. He spoke of the anatomy, arrangements, and comparison of uterine supports and the effect of force upon them, and the results of relaxation, whether due to mechanical force or inflammatory disease. He referred to the resistance offered by the pelvic organs and the pelvic floor to the force originating in the abdomen, its decrease and absolute loss following lesions of the pelvic floor. No single set of ligaments was sufficient to support the uterus, and no single operation would meet the indication of surgical repair in all cases. He described the operations suitable to various lesions and conditions.

The Clinical Results in the Treatment of Procidentia

of the Uterus by the Interposition Operation.—Dr. THOMAS J. WATKINS, of Chicago, drew the following conclusions: (1) Vesicouterine transposition should be made before much protrusion through the vaginal orifice resulted, as the prolapse rapidly increased after this took place; the more the prolapse the greater the dangers of recurrences following the operation. (2) Vesicouterine transposition cured cystocele, the most important pathological feature. (3) An occasional recurrence of the uterine prolapse would occur, except in cases where the vaginal canal could be practically obliterated. This recurrence, however, was not serious, as it could be easily remedied. (4) The operative technique should be adapted to each individual case.

A Study of the End Results of Interposition of the Uterus.—Dr. JOHN OSBORN POLAK of Brooklyn, N. Y., said that the normal supports of the uterus might be enumerated as follows: (1) The uterine ligaments, especially the uteropelvic and uterosacral, which maintained the cervix in its normal position. (2) The pelvic floor and pelvic fascia which made the pelvic diaphragm. (3) The supporting action of the adjacent pelvic organs. (4) The action of the intraabdominal pressure. And, finally, the axial relation of the uterus to the vagina. He drew the following conclusions: (1) That interposition should be limited to women at or past the menopause, with a relatively small uterus, and that when the procedure was elected in those still menstruating, sterilization by tubal ligation should be done at the time of the operation. (2) The cases of prolapse in which sliding took place in the postpubic cleavage plane, were not corrected by this procedure. (3) That the morbidity was wholly due to technical defects, namely, improper preparation, imperfect hemostasis, vesical injury, etc. (4) That in anteverting the uterus the anterior wall of the uterus should rest on the fascial plate just behind the pubis, the fundus should not be brought under the arch, as excessive anterior displacement not only favored recurrence, but antiflexed the uterus and interfered with drainage. (5) That the curettings from uteri about to be transposed should always be examined, as degeneration might occur, and hysterectomy was easy after this operation.

An Original Technique for Separately Uniting the Five Structures Injured in Lacerations of the Pelvic Floors.—Dr. BARTON COOKE HIRST, Philadelphia, said that for a number of years in his clinic in the University Hospital of Philadelphia he had had the recently delivered women placed upon an operating table in the dorsal gynecological position and anesthetized. This had been done in different series of patients on every day of the puerperium up to the seventh. As a result of this study, embracing hundreds of patients, it was possible to state the following facts in regard to lacerations; of the pelvic floor: The pelvic fascia over the levator ani muscle showed a split running parallel with the descending ramus of the pubis; the levator ani was torn loose from its attachment to the pubis and ischium, the injury began close to the bone and ran downward and inward toward the mid line of the posterior vaginal sulcus; the fascia between the levator and the deep transversus perinei showed a triangular split with the apex above. This deep transversus perinei was torn apart in the middle line and the two halves were retracted so that there was a gap between the ends of an inch or more; the junctions of the two halves of the superficial transversus perinei and of the bulbocavernosus muscles were torn apart if the perineal body was injured, as was commonly the case in laceration of the perineum. These facts being established, and it was only necessary to look at a sufficient number of recently delivered women to establish them, the rest of the problem was easy of solution. Such a denudation of the injured region must be made in secondary operations as to expose the component and anatomical parts, and then these component structures should be united separately at the site of the injury and restored to their original condition. But in either case the levator ani must be exposed by cutting through the pelvic fascia, under which it lay. There the belly of the muscle was attached to the portion arising from the pelvic bones; the deep transversus was brought out of its cavity in which it had retracted and was united in the middle line; the pelvic fascia between the levator ani and the deep transversus was united, and finally the perineal body was repaired. For convenience of illustration the sutures were represented as interrupted, but as a matter of fact the buried continuous tier catgut was used for the levator and the fascia; buried interrupted for the deep transversus and perineal body. The skin of the perineum was finally united over the catgut sutures by Michel's clamps.

President's Address: "Has the American Gynecological Society Done Its Part in the Advancement of Obstetrical Knowledge?"—Dr. J. WHITRIDGE WILLIAMS of Baltimore stated that in the conversion of cesarean section from the most dangerous operation in surgery to one whose results were so good, it was in imminent danger of being abused by "knife-loving" obstetricians, and by surgeons who knew nothing of the resources of obstetrics. The early accounts of tardy operations for the removal of a dead child from an exhausted and infected woman stood in marked contrast to the first elective operation performed by Lusk in 1887, but particularly to the long series of successful operations which were afterwards reported by many of the members. One of the most interesting phases of obstetrical history was afforded by the 51 papers upon extrauterine pregnancy. In these one could trace the evolution of a pathological curiosity into a condition of everyday occurrence. For purposes of analysis he classified the 346 obstetrical papers into 32 groups and presented them in tabular form. One of the most important factors in the lack of productivity was to be found in the system of medical education. Until recently university ideals were entirely lacking in the medical schools, and even now in many institutions affiliated with universities the connection was purely nominal. How many obstetrical departments were provided with proper accommodations for a sufficient number of patients for the instruction of students, with adequately paid and enthusiastic assistants, or with suitably equipped laboratories for research work, not to mention a salary for the director in any way commensurate for the ability and efforts necessary to supervise the work in anything like an ideal manner? Real university departments are just beginning to be organized in some other branches of medicine, but he knew of none in gynecology or obstetrics. From extensive investigation he knew that in most of the schools obstetrics was the least well cared for department, and must ordinarily be content with what was not wanted by others, while the professor was frequently regarded by his colleagues as being engaged in an almost unworthy pursuit. No doubt some professors were poorly trained and fulfilled their obligations lightly, but he knew many who took them seriously and who felt depressed whenever they considered the status of their department and their inability to do better work. So long as such conditions existed it was scarcely conceivable that many professors would be scientifically productive or would often be able to induce promising young men to devote themselves seriously to this branch of medicine, for the few men in this country who were really doing their duty did so with great personal sacrifices and against odds with which they should not have to contend. A third reason for the low state of American obstetrics was that this was the only country in the civilized world in which obstetrics and gynecology were sharply divided. While it was debatable whether a union of gynecology and obstetrics was feasible for those engaged in private practice, or would materially improve the matter in most medical schools as at present organized, there was no doubt in his mind that the professorial chairs in the university medical schools needed to be filled by broadly trained scientific men, who were prepared to give their time to their duty. He hoped to see a number of such institutions scattered over the land, and then no future president of this or any other society would be able to say that its members had not done their part in the advancement of obstetrical or gynecological knowledge.

The Clinical Manifestations of Disease of the Glands of Internal Secretion in Gynecological and Obstetrical Patients.—Dr. ROBERT TILDEN FRANK of New York gave a summary review of the influence of the individual glands of internal secretion (exclusive of the ovary) on (*a*) the anatomy of the genital organs; (*b*) the function of the genital organs, and (*c*) the secondary sex characters. He pointed out the differences of effect ascribable to the interaction of the various glands, the effects ascribable to the ovary, etc.

Iodine as a Sterilizing Agent in Supravaginal Hysterectomy, with Remarks upon Morbidity.—Dr. I. S. STONE, Washington, D. C., said he would not deal with the nearly perfect results of skin sterilization, but the application of iodine and alcohol to the vagina and uterine mucosa had been productive of results which appeared to approach the ideal. The patient was

brought to the operating table after the proper examinations had been made which showed her condition to be satisfactory for operation. She was placed in the lithotomy position, and a 25 per cent. (1.75 idodine) diluted alcoholic tincture of iodine was applied over the genitals and introitus vaginæ. The catheter was used immediately after this, and a perineal retractor introduced into the vagina and a volsellum used with which to grasp the cervix. The cervix was dilated to admit the conical nozzle of a two-ounce glass syringe. An ounce of the same 25 per cent. alcohol solution was then slowly injected into the cavity of the uterus. The fluid was not allowed to remain long nor was great force used. After the injection the cervical canal should be again gently dilated to make sure of the discharge of the excess of the solution. Every part of the vagina was exposed and the assistant who made this application to it made this feature of the technique an important one. The operation was preceded by a second application of iodine to the skin over the abdomen, the first having been made before the anesthetic was given. After this the operation was proceeded with as usual and a final application of the iodine-alcohol was made to the stump before closing the flaps if there was the slightest intimation that infectious matter had been handled, such as in an appendix, pus tube, etc. Finally, the iodine solution was applied over the closed abdominal incision before the usual gauze dressings were applied.

Complete Sterilization of the Skin by Iodine.—Dr. J. Wesley Bovée of Washington, D. C., related that in ten instances between May 9 and June 17, 1913, scrapings were made from skin prepared by the alcoholic solution of iodine (31.2 per cent.) and then subjected to thorough scrubbing with a strong solution of hyposulphite of soda until the iodine color was gone, the patients being anesthetized at the time for operation. The technique and findings were as follows: The following four specimens were used in the tests in each of the ten cases: (1) A small amount of the solution of hyposulphite of soda was put in a bouillon tube as a control. (2) Skin scrapings two minutes after the application of the second coat of iodine were put in some bouillon in tubes. (3) Same as 2, except scrapings were made 5 minutes after second painting. (4) Skin scrapings from the same field after thorough washing, scrubbing, and decolorizing by the sterile hyposulphite solution. At the end of five days incubation for the 40 specimens from the 10 patients showed absolutely no growth. In attempting to determine whether perfect sterilization of the skin could be produced by the painting with iodine, the following technique was used in preparing the specimens for the bacteriologist. The skin was lightly painted twice (the patient being anesthetized for operation) with the iodine preparation and a strip of skin 4 inches by ½ to 1 inch was cut from the median line of the abdomen 2 minutes after the last coat was applied. This strip was at once dropped into a container in which was 1 quart of physiological salt solution. Some of the same solution was previously put into a bouillon tube as a check. The tube and large container were taken to the laboratory and turned over to Dr. Briggs. In case 1 the iodine was of 10 per cent. strength, but in all of the other 11 it was the same as he had used for four years in surgical operations, 31.2 per cent. The interim between the coats varied from 16 to 92 minutes and the number of experiments was 12. In the last five a vigorous culture of *Bacillus subtilis* was rubbed into the skin to be removed 13 to 18 hours before the painting, and the area covered with a sterile dressing until the first coat of iodine was applied. These specimens were all transported a mile and not particularly well wrapped, which might in a measure account for the contamination of the control solution in three cases. This report showed that the salt solution containing the skin pieces was not inhibitory to bacterial growth; that the skin was sterile in practically every case, the few instances of growth being reasonably attributed to contamination, and that the *Bacillus subtilis* was killed. The spores of this latter species were known to be remarkably resistant, being able to withstand a 1-1000 solution of mercuric chloride for periods up to one hour. This notable resistance prompted their employment in this series of experiments. He had not been convinced that a 10 per cent. alcoholic preparation of iodine would not destroy these spores in from two to five minutes, even when painted on the skin. He was inclined to believe the extent of the germicidal power of the iodine depended more than a little on the manner of its application as well as upon the strength of the solution used. If the coating be made at first thick before a thin one is allowed to dry, penetration should be deeper or the deep penetration more perfect. If a thin coating was made the skin recesses might be but partly filled, and when evaporation of the iodine had occurred a thin, impermeable barrier of iodine was left. Whether this layer was free iodine or an albuminoid he was not prepared to state at this time. He expected later to determine whether a preparation of iodine stronger than used in this work would destroy the spores of *Bacillus subtilis* in the skin recesses.

The Behavior of the Abdominal Cutaneous Reflexes in Acute Conditions within the Abdomen and Pelvis.—Dr. Richard R. Smith of Grand Rapids, Michigan, said the behavior of this reflex had been noted in 175 cases in which diseased processes existed within the abdomen. The greater part of them were acute. The results had been compared with the findings at the operation which followed. This reflex and its behavior had been a test frequently used by neurologists, and attention had been called to it in local conditions within the abdomen by several writers. The reflex was obtained by stroking the skin of the abdomen, which normally produced an almost simultaneous contraction of the rectus and oblique muscles on the corresponding side. It was common to distinguish four reflexes—two above and two below. The reflex was very constant in healthy young people, though uncertain in very young infants and in old people or those with very relaxed or very obese abdominal walls—exceptions which might be definitely borne in mind. In the acute inflammatory diseases within the abdomen it was common to find this reflex involved to a greater or less extent, and the test might be made use of in the diagnosis and in estimating the extent of this lesion. He had found that in 75 cases of acute appendicitis the reflexes were more or less involved in 65. It was sometimes involved where rigidity was absent. The reflex was commonly impaired over the seat of the lesion when circumscribed, and in more extensive processes the other reflexes were also impaired. It was commonly, though not uniformly, involved in ectopic pregnancy cases. Its normal presence in cases of bowel obstruction would help to eliminate any acute infectious condition, and in the subacute infections of the pelvis he found the lower reflex almost uniformly absent. He believed that, although the test had a certain limited view, it might be of distinct advantage to the surgeon, and it was well worth his careful study.

Can Surgery Be Eliminated in the Treatment of Fibroid Tumors of the Uterus?—Dr. John A. McGlinn of Philadelphia read a paper on this subject in which he presented the following conclusions: (1) Surgery was the best treatment in fibroid tumors of the uterus and could not be supplanted by any other known form of treatment. (2) Roentgentherapy had an important place in the treatment of those tumors. (3) Surgeons and roentgenologists should not enter into competition with each other, but should work hand in hand for the relief of womankind.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

South Dakota State Board of Medical Examiners. *January 13 and 14, 1914.*

(*Continued from page 319*)

THERAPEUTICS AND PRACTICE.

1. Define hyperchlorhydria. Give the causes, symptoms, diagnosis, and treatment. 2. If summoned to a middle-aged person discovered in a comatose condition, explain how to recognize on what disease the condition depends, and give treatment for the uremic type of coma. 3. Differentiate between pyelitis and cystitis. 4. What are the four characteristic symptoms of exophthalmic goiter? Give the supposed etiology. 5. Differentiate catarrhal from croupous pneumonia. 6. On what symptoms would you base a diagnosis of typhoid fever? 7. How should acute nephritis accompanying or following scarlet fever be treated? 8. Name four diseases contraindications for general anesthesia, and state which of the four named you would consider the most important. 9. In the treat-

ment of syphilitic node or gumma, state which should be used, a mercurial or an iodide, and give the reason therefor. 10. Describe the treatment of a case of diphtheria.

OBSTETRICS.

1. Conduct a case of normal labor. 2. Would you use chloroform in labor? If so, why? If not, why? 3. What is meant by puberty? What is meant by nubility? What is meant by menstruation? At what age in this climate do these begin? 4. How many, and describe briefly the different circulations during fetal development and immediately after birth. 5. Give the usual length of time in normal gestation. Give maximum and minimum length of time. 6. Give positive signs of pregnancy. 7. What is placenta prævia, and how would you manage a case? 8. Give indication for the use of forceps. 9. Give indication for version, and how would you proceed to accomplish it? 10. Give cause for post-partum hemorrhage and how would you manage the same?

GYNECOLOGY.

1. What advice about bathing, sponging and exercise during normal menstruation would you give to a healthy young woman accustomed to warm tub-bath twice per week, cold sponging every morning and 2 miles' brisk walk daily? Why? 2. Give all causes of uterine hemorrhage. 3. Diagnose, treat and prognose chronic gonorrhea. 4. Diagnose, treat and prognose chronic leucorrhea. 5. Name all probable ailments and treat the most probable one: A patient, unmarried, aged 16, 5 feet 2 inches, 125 pounds, erect, pale, walks into your office at 4 p. m. Temperature 98.6°, pulse 100, respiration 20, mucous membranes pale, teeth bad, complains of having missed two menses, always regular before, sharp pain and tenderness 2 inches below ensiform process, constant for three weeks, worse at 4 p. m. daily, better after eating. Pain in lumbar, sacral, uterine, and ovarian regions; no discharge. Dyspnea on exercising; no heart-murmurs; constipated as a rule, sometimes blood in stools. Nausea in morning and when pain is bad, vomits almost daily, some days several times. Mother was sick in same way at same age for two years. Tired all the time.

SURGERY.

1. A man is brought into your office with both lower limbs crushed off, having fallen under a passing engine; he is in full shock, has lost considerable blood, and is almost pulseless. What would be your immediate treatment? 2. Called to attend a patient who is suffering from a troublesome epistaxis. Describe the method you would pursue to check it. 3. How would you treat a perforating gunshot wound of the abdomen? 4. Describe a Colles' fracture and give your treatment for same. 5. How would you manage a case of empyema? 6. Give the technique of an operation for the cure of a mastoid abscess. 7. Give the technique of taxis in inguinal hernia. 8. Describe the operation for strangulated hernia. 9. Describe a proper method of amputating the hip-joint. 10. Under what circumstances would you consider circumcision a proper procedure?

ANSWERS.

REGULAR THERAPEUTICS AND PRACTICE.

1. *Hyperchlorhydria* is the condition in which the acidity of the gastric juice is greater than normal. It is associated with neurasthenia, gastric ulcer, gastric dilatation, hysteria, locomotor ataxia, and other disorders. It is due to local irritation, nervous strain, eye-strain, or gastritis. There is a sense of weight and burning in the epigastrium occurring an hour or two after meals, particularly after the chief meal of the day; vomiting and eructations of sour fluid may occur. The diagnosis is made by an analysis of the gastric contents, and finding an excess of hydrochloric acid. Treatment consists in the removal of the cause, a milk diet, and sodium or potassium bicarbonate or nitrate of silver.

2. The following table (from Eisendrath's *Surgical Diagnosis*) gives the diagnosis:

COMA FROM INTRACRANIAL INJURY.	APOPLECTIC COMA.	UREMIC COMA.	ALCOHOLIC COMA.	OPIUM POISONING.	DIABETIC COMA.
Deep coma; may have history of onset after fall or injury. Evidence of fracture of vertex or base.	Deep coma; sudden onset. If any injury, only a scalp wound.	Deep coma. Slow onset unless convulsions have preceded the coma.	Can be aroused by supraorbital pressure unless very profound.	Can be aroused unless very deep.	Deep coma. Sweetish odor to breath.
Pupil dilated on side of lesion. Choked disc.	Pupils unequal or dilated. Contracted in hemorrhage into the pons.	Albuminuric retinitis.	Pupils normal or somewhat dilated.	Pupils contracted to pinpoint size.	
Pulse very slow.	Pulse full and slow, often arteriosclerotic high-tension pulse.	Pulse rapid.	Pulse more rapid than normal and full.	Pulse rapid, may be irregular.	
Respiration slow and stertorous.	Respiration slow and irregular.	Respiration frequent and irregular.	Regular respiration.	Respiration very slow — may be 6 to 8 per minute.	
Temperature higher —101°.	Temperature higher on paralyzed side, but lower in rectum.		May be low or normal.		
Urine normal or contains trace of albumin.	Urine contains trace of albumin, but may be same as in uremia.	Urine shows albumin, casts, and low urea percentage.	Normal.	Normal.	Urine contains a variable amount of sugar and diacetic acid.
Hemiplegia on opposite side to that of injury. If contusion of brain is also present, may have generalized convulsions.	Hemiplegia with convulsions on one side.				

Treatment of uremic coma: One drop of croton oil diluted with sweet oil should be placed on the patient's tongue; a hot pack should be applied, and pilocarpine administered; inhalations of chloroform may be necessary; digitalis, caffeine, nitroglycerin, or sparteine may be given; diuretics are required.

3. In *pyelitis* the pus comes from the kidney, and the urine is turbid and fairly uniformly mixed with pus, washing out the bladder hardly affects the quantity of pus. In *cystitis*, pus in the urine appears at the end of micturition, and if the bladder is washed out the quantity of pus in the urine is markedly diminished.

4. The *four characteristic symptoms of exophthalmic goiter* are: Protrusion of the eyeballs, enlargement of the thyroid gland, increased frequency of the heart beat, and muscular tremors. The *supposed cause* is some perversion of function of the thyroid gland.

5.

CROUPOUS PNEUMONIA.	CATARRHAL PNEUMONIA.
Generally a primary disease.	Generally secondary (to bronchitis or an infectious disease).
Age has little influence.	Generally found in very young or very old.
Sudden onset.	Gradual onset.
Fever is high and regular.	Fever is not so high, and is irregular.
Ends by crisis between sixth and tenth day.	Ends by lysis, at no particular date.
Generally only one lung affected.	Generally both lungs affected.
The physical signs are distinct, and there is a large area of consolidation.	Physical signs indistinct, and the evidences of consolidation are indefinite.
Sputum is rusty.	Sputum is rather streaked with blood.

6. A *diagnosis of typhoid may be based on:* The characteristic rose spots, the temperature chart, Widal's reaction, Ehrlich's diazo reaction.

7. Acute nephritis accompanying or following scarlet fever should be treated by rest in bed, milk diet, hot packs, hydragogue purgatives (but not mercurials); potassium acetate and spirit of nitrous ether are useful.

8. The following *contraindications* for ether and chloroform are from Hare's "Practical Therapeutics": "*Ether* should not be used by inhalation in bronchitis or acute nephritis because of its irritant properties; in peritonitis or gastritis, because it is apt to induce vomiting; in aneurysm or in the presence of marked vascular atheroma, because it may rupture a blood-vessel by raising arterial pressure; nor in diabetes, lest it produce diabetic coma; and if anemia is present and an examination of the blood shows that the hemoglobin is below 50 per cent., the use of the drug should be avoided if possible. *Chloroform* is not to be used in cases of fatty heart or dilatation of the heart, in those with a known idiosyncrasy, nor in the so-called lymphatic persons with overgrowth of lymphoid tissues, as, for example, adenoids. In the latter case it is particularly apt to cause sudden death. In valvular disease of the heart chloroform may be used with caution, although ether is preferable. Given a case of valvular disease that must be subjected to operation, the chances are bettered with an anesthetic than without it, as the pain and mental shock are worse for the heart than is the anesthetic."

9. "If at any time during the case there appear tertiary symptoms, the patient should be put on mixed treatment. In any case, after two years of mercury add iodide of potassium to the treatment. White's rule is to use mixed treatment for at least six months (if any symptoms appear), the six months' course dating from their disappearance. This emphasizes the fact that the iodide alone will not cure tertiary syphilis."—(Da Costa's *Surgery.*)

10. *Treatment of diphtheria:* The patient should be in bed and isolated; the family should be quarantined; infected articles should be soaked in some antiseptic solution and then boiled; a milk diet is indicated; the nose and throat should be kept clean by the use of some mild antiseptic solution; calomel in divided doses should be given to keep the bowels open; tincture of the chloride of iron is indicated; and early administration of diphtheria antitoxin in adequate doses (3,000 to 10,000 units) must be given at once; if there is no improvement within twelve hours, the dose must be repeated.

OBSTETRICS.

1. *The patient* should receive a full bath before labor begins and all bed-clothing and personal clothing should be clean. If there are any pathological discharges from the genitals, the vagina should be thoroughly scrubbed with tincture of green soap and hot water, followed by a mercuric chloride douche (1:2000); this followed by a douche of sterile water. The physician's hands should be scrubbed for ten minutes with tincture of green soap and hot water, followed by alcohol, and immersion in mercuric chloride (1:1000). All instruments should be boiled for ten minutes or immersed in mercuric chloride 1:1000 for half an hour. Examinations should be made when necessary to determine the position, presentation, size of the fetus, etc.

During the first stage a rectal enema of soapsuds with turpentine (5i) should be given, and when the os is dilated to the size of a silver dollar, the patient should be placed in bed, lying upon the side toward which the fetal back looks. If the pain is severe, chloral hydrate (gr. 15) may be given every half-hour for three doses.

During the second stage, examinations should be made only when necessary. In multiparæ, the membranes may be ruptured with the finger or with some aseptic instrument. Care should be taken not to injure the child's scalp or the lower uterine segment. The pain may require the administration of chloroform or ether, but not to the extent of complete anesthesia. The expulsive force of the abdominal walls may be increased by directing the patient to pull upon a sheet firmly secured to the foot of the bed. Attempts may be made to prevent laceration of the perineum by making firm backward and upward pressure against the occiput during the pains; by restraining voluntary expulsive efforts during the pains; and by securing expulsion of the head between the pains. The head should be supported when born; the eyes should be cleansed with sterile water; and if the cord is coiled about the neck, it should be loosened or slipped over the head. Delay in delivery of the shoulders may be overcome by stimulating the uterus by friction through the abdominal wall or traction. The cord is ligated and cut when pulsation has ceased, and the child is placed by the mother's side with its face turned away from the maternal discharges.

During the third stage, 5i of fluid extract of ergot is administered and irritation of the uterus by friction through the abdominal wall is practised for ten to fifteen minutes. If the placenta is not expelled by this time, the uterus is firmly grasped between the thumb and four fingers and compressed. Firm pressure is then made from above downward and backward in the direction of the pelvic canal. This usually causes delivery of the placenta. A vulvar pad of salicylated cotton and carbolized gauze and an abdominal pad and binder are then applied.—(*Pocket Cyclopedia.*)

2. I would certainly use chloroform in labor if it were indicated. The main indication is to deaden the severe pains before the actual birth of the child, and to render the patient unconscious during the birth of the head, and also in abnormal and operative cases.

3. *Puberty* is the period when the child becomes sexually mature; and, in the case of the female, when menstruation commences. It begins at about fourteen or fifteen years of age.

Nubility is the period when a woman is mature, and fit for marriage and pregnancy. It begins at about twenty years of age.

Menstruation is a periodical disturbance in the female, characterized by a bloody mucus discharge from the uterine cavity; it lasts during the period of woman's sexual activity, but is temporarily suspended during pregnancy and early lactation. It begins at about fourteen or fifteen years of age.

4. *The fetal circulation:* "The arterial blood coming from the placenta to the fetus travels along the umbilical vein to the liver. After giving off several branches to the left lobe it divides into two streams, the larger joining the portal vein and thus entering the liver, the smaller passing directly into the inferior vena cava through the *ductus venosus*. In the inferior vena cava the blood carried by the hepatic veins and ductus venosus mixes with the blood which has circulated through the lower extremities. On entering the right auricle the blood of the inferior vena cava is directed by the Eustachian valve, through the foramen ovale into the left auricle, and from thence into the left ventricle. The left ventricle forces it into the aorta, and it is then distributed to the head and upper extremities, a small quantity only passing into the descending aorta. The blood which has circulated through the head and upper extremities returns to the heart along the superior vena cava, the blood then passing into the right ventricle and pulmonary artery. A small part of the blood in the pulmonary artery is conveyed to the lungs, but the major part passes through the ductus arteriosus into the aorta at the commencement of the descending portion. This blood is distributed to the lower extremities, a certain portion of it entering the hypogastric arteries and being conveyed to the placenta."—(Ashby's *Physiology.*)

The changes occurring in the circulation at birth are: The hypogastric arteries become obliterated, the foramen ovale closes, the Eustachian valve atrophies, the ductus arteriosus and ductus venosus become impervious and shrivel up.

5. A normal pregnancy usually lasts about 280 days or ten lunar months; this is only approximate. Cases have been reported where a pregnancy terminated in the birth of a live child at the sixth month, and it is also possible for a pregnancy to be prolonged eight weeks. There are no absolute limits.

6. *Positive signs of pregnancy:* (1) Hearing the fetal heart sound; (2) active movement of the fetus; (3) ballottement; (4) outlining the fetus in whole or part by palpation; and (5) the umbilical or funic souffle.

7. *Placenta prævia* is the condition in which the placenta is attached in the lower uterine segment, and may be near or over (partially or completely) the internal os. *Symptoms:* Sudden hemorrhage, accompanied by syncope, vertigo, restlessness, and feeble pulse. *Treatment:* Stop the hemorrhage by vaginal tampon; this must be tight and thorough. *Accouchement forcé* is indicated; this consists of dilatation of cervix, version, and immediate extraction of the child.

8. *Indications for the use of forceps* are: "1. *Forces at fault:* Inertia uteri in the presence of conditions likely to jeopardize the interests of mother or child. (*a*) Impending exhaustion; (*b*) arrest of head, from

feeble pains. 2. *Passages at fault:* Moderate narrowing, 3¼ to 3¾ inches, true conjugate; moderate obstruction in the soft parts. 3. *Passenger at fault:* A.—Dystocia due to (*a*) occipito-posterior, (*b*) mento-anterior face, (*c*) breech arrested in cavity. B.—Evidence of fetal exhaustion (pulse above 160 or below 100 per minute). 4. *Accidental complications:* Hemorrhage; prolapsus funis; eclampsia. All acute or chronic diseases or complications in which immediate delivery is required in the interest of mother or child, or both."—(From Jewett's *Practice of Obstetrics.*)

9. The *indications for version* are: (1) In transverse presentations; (2) in placenta prævia; (3) in malpresentations of the head; (4) in simple flattened pelvis, and in minor degrees of pelvic contraction; (5) in prolapsed funis; (6) in sudden death of the mother, and (7) in any case where speedy delivery is imperative.

Braxton Hicks' method of bipolar (podalic) version: "The patient should be placed in the lithotomy position and be deeply anesthetized, to relax the parts and allow the whole hand to be pushed into the vagina. The external hand is placed over the breech, so as to depress it; while the presenting part is tilted away from the brim by the fingers inserted through the os. The fingers press against the front of the child and flexion is lessened. When the head is out of the brim the external hand can be used to elevate it towards the fundus. As soon as a knee or foot comes within reach of the internal fingers, it should be caught and brought into the brim, the membrane being ruptured at the same time. If the os is fully dilated, delivery may be finished at once, as in an ordinary breech case; but if the os is only partially dilated, it must be left to nature, to allow of dilatation."—(Jardine's *Delayed and Complicated Labor.*)

10. POST-PARTUM HEMORRHAGE. *Causes:* Anything interfering with the firm contraction of the uterus after the expulsion of the child; retained placenta, or membrane, or clots; weakness of the uterine muscle; rapid labor; delayed labor; poorly developed uterine muscle; inflammation or disease of uterus.

Treatment: Grasp the uterus at once, through the abdominal wall, and massage it firmly. Anything in the uterus should at once be cleaned out. Pass one hand into the uterus, and with the other on the outside make firm pressure. A hypodermic of ergotin or ergot can be given by an assistant. An intrauterine douche of hot sterilized water (about 115° F.) may be given. Sometimes a very thorough packing and plugging of gauze of uterus and vagina may be necessary. Whatever is done must be done promptly; and everything likely to be needed for this emergency should be prepared beforehand in every labor.

GYNECOLOGY.

1. Unless there was some positive contraindication I would advise the healthy young woman to continue her bathing, sponging, and exercise during normal menstruation just the same as at other times.

2. The following (from *The Cyclopedia of Medicine and Surgery*) is a useful classification of uterine hemorrhages, and also gives the causes of the same:

I. *Hemorrhages complicating pregnancy, labor, or the puerperium:*

A. Hemorrhages of pregnancy: Caused by (1) placenta prævia; (2) premature separation of a normally situated placenta; (3) apoplexy of the decidua or placenta.

B. Hemorrhages of labor: Caused by (1) placenta prævia; (2) premature separation of a normally situated placenta; (3) relaxation of the uterus; (4) laceration of cervix; (5) rupture or inversion of the uterus.

C. Hemorrhages of the puerperium: Caused by (1) retained secundines; (2) displaced uterus; (3) displaced thrombi; (4) fibroid tumors; (5) hypertrophied decidua; (6) carcinoma.

II. *Hemorrhages occurring in the non-pregnant woman:*

A. In virgins before the age of thirty: Caused by (1) uterine congestion, the result of cold or exposure; (2) endometritis; (3) polypi and fibroid tumors.

B. In married women before the age of thirty: Caused by (1) subinvolution; (2) laceration of the cervix; (3) endometritis; (4) retrodisplacements of the uterus; (5) polypi and fibroid tumors.

C. In women after the age of thirty: Caused by (1) carcinoma of the cervix; (2) carcinoma of the body of the uterus; (3) sarcoma of the uterus.

3. GONORRHEA. *Symptoms:* Pain and burning in the vulva; pain and burning on micturition; dyspareunia; yellowish or greenish discharge, in which the gonococcus can be found; the vagina is hot, red, swollen, and tender. *Possible results:* Cystitis, urethritis, vulvitis, endometritis, salpingitis, septic peritonitis, sterility, condylomata of vulva, abscess of Bartholin's glands. *Diagnosis* is made from the symptoms, particularly from finding the gonococcus in the discharge. It is *so serious*, on account of the possible results, enumerated above; it often leads to chronic invalidism, and may be the cause of death.

Treatment: Rest, if possible in bed; freedom from alcoholic or sexual excitement; a mild and unirritating diet; salines and diuretics; plenty of water to drink; a warm sitz bath; douching of vagina with about a gallon of a 1:5000 bichloride solution, or of borax (1 dram to the quart), or of potassium permanganate (1 per cent. solution); the douche is to be taken in the recumbent position.

4. *Leucorrhea* is any discharge from the genital canal other than the menstrual discharge. Chronic cases are hard to cure, and much depends on the recognition and removal of the cause. *Treatment:* "Generally, local and general treatment should be combined. The patient should have plenty of substantial food, except when the cause is plethora. Her bowels should be kept open. She should be much in the open air. She should have woollen underwear. She should occupy a dry, sunny room. Change of air and pleasant surroundings have a beneficial effect. Sea baths and other cold baths are useful, but in rheumatic patients Turkish or Russian baths are better. Tonic medicines should be prescribed. Aletris cordial (a teaspoonful t. i. d.) and fluid extract of hydrastis (m. xx) sometimes arrest the discharge. In most cases a local treatment is necessary, such as applications, painting with tincture of iodine, the insertion of pledgets or suppositories containing astringents, vaginal injections of hot water or astringent fluids. A narrow cervical canal should be dilated, a diseased mucous membrane curetted or cauterized. The whole mucous membrane of the cervix may be cut away."—(Garrigues' *Gynecology.*)

5. The history is too inadequate to serve as a basis for any diagnosis. The patient may be suffering from chlorosis, piles, gastric ulcer, pregnancy, or several other conditions. As the question stands the candidate can only guess.

SURGERY.

1. "An important question is often raised as to the advisability of performing an operation during shock. As a general rule, it may be stated that operation should be deferred until reaction has come on, unless the presence of the injured organ, such as a badly crushed limb, is evidently prolonging the condition. Under these circumstances a hypodermic injection of morphine may improve matters by relieving pain; otherwise the local lesion should be at once dealt with, and it will be often found that, as the patient passes under the influence of the anesthetic, the pulse improves, and the state of shock disappears, the anesthetic shielding the medullary centres from the painful afferent stimuli."—(Rose and Carless' *Surgery.*)

"Should we operate during shock? We should only do so when death without instant operation is inevitable. It is not wise, in the author's opinion to amputate during shock. A tourniquet or Esmarch bandage should be applied, and attempts be made to bring about reaction, and when reaction is obtained the amputation should be performed. It is only just to say that some eminent surgeons oppose this rule. Roswell Park says that "shock is often alleviated by the prompt removal of mutilated limbs which, when still adherent to the trunk, seem to perpetuate the condition."—(Da Costa's *Modern Surgery.*)

2. *To arrest epistaxis:* (1) Try to cauterize the bleeding point: (2) plug the nasal cavity with gauze soaked in adrenalin; (3) inject into the nares a solution of peroxide of hydrogen; (4) plugging the nares, anteriorly and posteriorly; (5) an inflating plug may be used.

3. *Perforating gunshot wound of the abdomen.* "The treatment, even without symptoms of visceral injury, is immediate enlargement of the wound, in order to explore the abdomen, check hemorrhage, and close such visceral perforations as may be found. The abdomen is then flushed with salt solution, and closed or drained, according to the amount of soiling present. If the omentum protrudes it should be ligated

and removed, while coils of intestine should be carefully washed with salt solution and returned to the cavity. In cases in which there is doubt as to whether or not a wound enters the peritoneal cavity, such wound should be enlarged and the diagnosis positively made, being prepared at the same time to treat any visceral injuries that may be found. In gunshot wounds on the battle field an exception has been made to the rule of immediate exploration, because it has been found that the chances of recovery are somewhat better without than with operation undertaken in the absence of proper facilities."—(Stewart's *Surgery.*)

4. *Colles' fracture* is a transverse fracture at lower end of radius; it is due to falls on the outstretched palm. The line of fracture is about an inch above the wrist, and runs obliquely downwards from behind. The lower fragment is driven backwards and upwards, and rotated to the radial side, carrying the hand with it into the position of abduction, and leaving the tip of the radius at the same level as, or higher than, the tip of the styloid process of the ulna. The internal lateral ligament of the wrist is ruptured or the styloid process torn off. The fracture is usually impacted, the upper fragment being driven into the lower. The deformity is characteristic, viz.: (1) the hand is abducted; (2) the styloid process is on the same level as, or lower than, the tip of the radius; (3) the upper end of the lower fragment projects above the back of the wrist; on the front is a corresponding depression, while above it the upper fragment projects forward. Union occurs readily, but it is common to get deformity and adhesions about the site of fracture. *Treatment:* Disimpaction and reduction are brought about by grasping the hand by the "shaking-hands" grip, extending and adducting the hand and lower fragment. The arm is then fixed on a splint. It is very important in this fracture to start massage and passive movement not later than the end of the first week, to prevent stiffness. Union is firm in three weeks.—(*Aids to Surgery.*)

5. EMPYEMA. "Treatment should be undertaken without delay. Aspiration seldom cures, but may be undertaken where the dyspnea is great, and an anesthetic given afterward for the excision of a piece of rib. Drainage is always necessary, and is best done by excising a portion of the fifth or sixth rib in the mid-axillary line. The patient should be allowed to come round quickly from the anesthetic, so that the coughing which occurs will expel the masses of coagulated lymph and help to expand the lung. A big drainage-tube is then inserted. Daily dressings are necessary, but irrigation of the cavity is seldom needed. If, because of delay in treatment, the cavity does not soon close, Estlander's operation, or some modification, must be performed. The wound must be enlarged and a number of ribs exposed, and sufficient of them removed to convert the cavity into a pyramidal one, the base of which is the open wound. This is packed with gauze and allowed to heal from the bottom. If the operation has to be extensive, the flaps are allowed to fall back upon the granulating surface of the lung, and in these cases marked scoliosis and weakness of that side of the chest follow."—(*Aids to Surgery.*)

6. MASTOID ABSCESS. *Operation:* A semicircular incision of the soft parts is carried from a point about one-half inch above the attachment of the auricle, backward and downward, keeping parallel to the auricular attachment and terminating at the tip of the mastoid. The periosteum is now elevated or dissected from the bone and the osseous structure thoroughly exposed by means of retractors, which are held by an assistant, the auricle being pulled forward so as to lie upon the side of the head. The hemorrhage is controlled by the use of hot sponges and artery forceps. The surface of the mastoid is thoroughly examined for areas of necrosis or the existence of a fistulous opening, especially if a fluctuating swelling obtains previous to the operation. If these exist, the openings are enlarged by means of a gouge or a chisel and mallet, and followed inward to their origin. Should the surface present a healthy appearance, the primary opening of the mastoid is made into the antrum by means of the chisel, the point of entrance being effected just below the line of the superior wall of the meatus and about one-quarter of an inch backward from the posterior wall or anterior edge of the mastoid bone. When the antrum has been exposed, the cortex of the mastoid is chiselled away from this point downward toward the tip until a sufficient amount has been removed to expose all parts of the mastoid process. The cells are now all broken down, and every vestige of a necrotic or granulating area is completely eradicated. A free communication of the antrum with the tympanum should be established, which may be proved by syringing an antiseptic solution into the antrum, when it will escape from the external auditory meatus through a previous perforation of the drum head. The cavity of the mastoid is packed with sterile gauze, and the flaps of overlying tissue allowed to regain their former position, when a gap remains between their edges, through which the dressings may be changed.—(Alling and Griffin.)

7. "*Taxis*, or the manipulations for the reduction of a hernia, should always be gentle, and should rarely be tried for more than five or ten minutes, because of the danger of rupture of the bowel. It should not be employed in the presence of inflammation or gangrene. Reduction is facilitated by having the patient recumbent, the thighs flexed (and that of the affected side adducted in femoral or inguinal hernia), and the pelvis raised. The administration of opium and belladonna and the application of heat or cold also are useful in securing relaxation. One hand is used to steady the neck of the sac, while with the other the hernia is compressed and pushed back into the abdomen. In direct inguinal and umbilical herniæ the pressure is backward; in oblique inguinal hernia it is upward, outward, and backward; in femoral hernia it is at first downward and inward, then upward and backward. The successful reduction of bowel is sudden and accompanied by a gurgle; omentum is forced back slowly without gurgling."—(Stewart's *Surgery.*)

8. STRANGULATED HERNIA. "Operative treatment should be undertaken at once when gentle taxis has failed. An incision is made over the sac, which is then opened. There is usually fluid in the sac, so there is no danger of wounding the gut. The fluid is washed away ,then the cause of strangulation is made out, and a hernia knife guided up to it by a finger or broad hernia director. The constriction is nicked in one or two places and the gut is drawn down, so that the site of strangulation may be examined. Omentum is ligatured and removed. According to the condition of the intestine the further treatment differs. (1) If the gut, though black, has not lost its polish, it is reduced by gently compressing it to remove the edema. (2) If gangrene is suspected, the strangulated portion must be resected, and end-to-end union established. (3) If the gut is undoubtedly gangrenous, one of two methods must be adopted: (1) if the patient is profoundly collapsed and will not bear a prolonged operation, an artificial anus is established by dividing the constriction outside the sac, so as not to open the peritoneal cavity. The loop of bowel is then opened to give free exit to the feces. Most of the cases which have to be treated in this way are so bad before treatment is commenced that a fatal termination must be expected. (2) If the patient can possibly stand it, immediate resection gives the best chance, and with Murphy's button or a bobbin much time can be saved. A radical cure is advisable after relief of the strangulation.—(*Aids to Surgery.*)

9. *Hip-joint amputation:* "The most satisfactory method in the great majority of cases is Wyeth's, in which a constrictor is held in place by the preliminary passage of two steel pins. The outer pin is inserted an inch and a half below and a little internal to the anterior superior spine of the ilium, and is brought out just back of the great trochanter. The inner pin is entered one inch below the level of the crotch and internal to the saphenous opening, and it emerges an inch and a half in front of the tuberosity of the ischium. . . . After the limb has been emptied of blood by holding it in a vertical position for five minutes and stroking it from the periphery toward the body, the constricting band is fastened about the limb above the pins. . . . The hip is brought well over the edge of the table, a circular incision is made down to the deep fascia, six inches below the constricting band, and is joined by a longitudinal skin-cut reaching from the band to the level of the circular incision, and the cuff is reflected to the level of the lesser trochanter. The muscles are cut by a circular sweep at the level of the retracted cuff, the capsule of the hip-joint is opened freely, the cotyloid ligament is cut posteriorly, the thigh is bent upward, forward, and inward to dislocate the head of the bone, the round ligament is incised and the limb removed."—(Da Costa.)

10. *Circumcision is indicated* in congenital phimosis; when the prepuce is long, inflamed, or edematous.

THE IMMEDIATE RESULTS OF SALVARSAN TREATMENT OF SYPHILIS, AS JUDGED BY THE WASSERMANN REACTION. USING A CHOLESTERIN-FORTIFIED ANTIGEN.

BY E. G. STILLMAN, M.D.,
NEW YORK.

(From the Pathological Department, Presbyterian Hospital Columbia University, N. Y.)

THIS report covers one year's work from February 1, 1913, to February 1, 1914, during which year forty-seven cases of syphilis were treated by two or more salvarsan injections. In only five instances was the Wassermann reaction rendered negative, and in thirty-six cases the reaction remained unchanged.

Of the small number of serological reports on the action of salvarsan, most are lacking in important details. Many writers, for instance, do not state whether the original technique of Wassermann or some modification was followed. Furthermore, as some antigens uniformly give less positive results than others, it is most essential to know what antigen is used; also the exact number of salvarsan injections, and because of its effect on the Wassermann reaction, any mercurial medication should be stated in full. It is to be hoped that in future, reports on the salvarsan treatment of syphilis will be given in greater detail. Not until this is done can a comparison of different methods of treatment be made. Fox[1] gives an excellent form of tabulation which, for the sake of uniformity, it would be well to follow. I have followed it as nearly as I could in my own tables.

Speaking of the effect of neosalvarsan alone Fox reports that with only four intravenous doses of neosalvarsan out of fourteen cases (eight in the secondary stage, and five tertiary cases) giving a 4+ Wassermann reaction, at the end of some months, seven were changed to 3+ and three to 2+, one to 1+, and one to negative. In these Wassermann tests an alcoholic extract of normal heart was used as an antigen. Yet he believes that the effect of neosalvarsan on the Wassermann reaction is considerably weaker than that of a corresponding amount of salvarsan. Using an alcoholic extract of syphilitic liver Nichols and Charlet[2] obtained more definite results. In three cases in the first stage showing a 3+ before treatment, after receiving 4, 5, and 4 injections of salvarsan they respectively showed 1+, 2+, and 2+ positive Wassermanns. After receiving four injections of salvarsan two cases in the second and third stages remained 2+ and 3+ respectively, two dropped from 3+ to 2+, while one rose from 2+ to 3+. Of the two cases they report in the fourth stage, one changed from 2+ to negative after nine injections, while the other rose from a negative, with five injections, to a 3+.

This antigen may be criticised as being too strong, but competent workers such as Walker and Swift,[3] and Kolmer, Laubaugh, Casselman, and Williams[4] consider it perfectly satisfactory and advocate its use.

Sachs[5] first applied the method of fortifying antigens by the addition of cholesterin to the crude alcoholic extract of normal beef heart. McIntosh and Fildes[6] also found that fortified alcoholic extracts of human heart were much superior to alcoholic extract of normal heart, of syphilitic livers, or the lecithin-cholesterin mixture of Browning. Walker and Swift[3] conclude that "the addition of cholesterin to an alcoholic extract of heart or fetal liver increases the antigenic value of the extract in the Wassermann reaction." They also state that "Both the human heart and the guinea-pig heart extract are superior to beef heart extract when the same amount of cholesterin is added to each of the extracts." Kolmer, Laubaugh, Casselman, and Williams[4] concluded that cholesterinized alcoholic extract of human, pig, and beef hearts, in the order named, are to be preferred.

The Wassermann reactions here reported were all done with an alcoholic extract of guinea pig's heart plus 0.4 gram cholesterin per 100 c.c. of alcoholic extract. The only modification of the original Wassermann was that half quantities of the reagents were used. For the hemolytic system a 5 per cent. suspension of sheep cells was used. Using an amboceptor whose strength had been determined by titration against complement of known strength, daily preliminary titrations of complement were made. In doing the test itself 2 units of amboceptor and 2 units of complement were used and .5 c.c. of a 10 per cent. suspension of the alcoholic extract of guinea pig heart plus cholesterin. The sera, complement, and antigen were incubated for one hour in a water bath, and after the addition of the hemolytic system, the tests were incubated for a second hour. The final readings were made the next morning.

In reading the results no hemolysis was reported as 3+, 50 per cent. hemolysis at 2+, less than 50 per cent. hemolysis as +, and complete hemolysis as negative.

All the cases of syphilis, both in the dispensary and in the hospital over a period of one year, which gave a positive Wassermann reaction with this cholesterin antigen before treatment was begun and who received two or more salvarsan or neosalvarsan injections are reported. No attempt has been made to compare the effect of salvarsan and neosalvarsan on the Wassermann reaction. Because of its effect on the Wassermann reaction the

amount of salicylate of mercury administered is shown. Even in this small number of cases there are three instances where the Wassermann was negative directly after a course of mercury. Unfortunately it is impossible to tell if the dispensary patients are receiving any treatment elsewhere which might modify their Wassermann reactions. During their treatment these cases in most instances had frequent Wassermanns done. As many of the dispensary cases are still undergoing treatment, the final Wassermann reactions given are those taken after the last tabulated salvarsan injection. The Wassermanns on the hospital cases were all done before their discharge from the hospital.

In a subsequent report I shall give the late results of treatment of these cases. The large majority of the cases are infections of long standing. Table I shows the number of cases who received from two to twenty-one injections of salvarsan and neosalvarsan with the resulting effect on the Wassermann reaction.

Of the dispensary cases, three primary cases, one secondary case, and one tertiary case were rendered negative. Three of the four primary cases were rendered negative and in the fourth case, which remained positive, there is some doubt if this was a recent infection as the lesion on the lip was not a typical hard chancre. Of the five secondary cases one changed to negative, one remained 2+, while three remained 3+ positive.

The proportion of positive cases among the tertiary cases is very high, as out of eighteen cases showing a 3+ positive before treatment, thirteen remained 3+ positive, two dropped to 2+, only one was rendered negative, while one case rose from a 2+ to a 3+ positive. Of the nineteen hospital cases, all in the tertiary stage, giving a 3+ positive reaction before treatment, eighteen remained 3+ positive and one dropped to a 2+. But nine hospital cases show clinical improvement. In the case of syphilis of the liver (No. 37) the liver was reduced in size, and case No. 44 felt perfectly well

at the time of discharge. In the case of transverse myelitis (No. 46), whereas before treatment the patient could not retain his urine, at the time he left the hospital he could hold his urine for about two hours and his muscles were noticeably stronger.

Although the cases here reported are too few in number to draw any definite conclusions from, yet they seem to show that, when a cholesterin fortified antigen is used in the Wassermann reaction:

1—Early cases of syphilis treated by salvarsan injections may be changed from a 3+ positive to a negative.

2—Old cases of syphilis treated by numerous salvarsan injections show little or no improvement from a serological standpoint.

AUTOIMMUNIZATION IN RESPIRATORY INFECTIONS.*

By CHARLES H. DUNCAN, M.D.,

NEW YORK.

In former papers the writer reported cures of many patients suffering from various infections, with the natural, unmodified toxin complex, or remedy that is supplied by the patient's body. In the present paper he will take up the autotherapeutic treatment of patients suffering from infections of the respiratory tract. This method of treating patients was discovered by the writer by following the rules already formulated in the regular development of autotherapy.

Before taking up the technique of this treatment, we will state briefly the principle upon which cures made by autotherapy rest, and give additional reasons for its great therapeutic value. The author believes that a natural, or spontaneous cure of an infectious disease is due to the entrance into the blood stream of unmodified toxic substances, developed in the focus of infection. When this occurs the power of the blood serum is raised, and the activity of the leucocytes is stimulated, with the resultant development of specific antibodies. Autotherapy, or autoimmunization, the physician's method of treating the patient, is based on Nature's method of cure; for by autotherapy the patient is inoculated with unmodified toxic substances elaborated within his own body by the action of the infecting agent on his body tissues. By autotherapy the physician simply inoculates the patient with the same unmodified toxic substances that Nature utilizes when a spontaneous cure is brought about; these may be obtained by filtering the pathogenic exudate of the disease through a Berkefeld filter. The bacteria-free filtrate contains all of the unmodified toxins from all of the micro-organisms, both causative and complicating, that are in the focus of infection, and when this is injected hypodermically, the same thing occurs as when Nature cures, namely, the power of the blood serum is raised, the activity of the leucocytes is stimulated by the action of specific antibodies to overcome or combat all of the microorganisms from which the patient suffers. As more antibodies are developed when the toxins are placed in subcutaneous tissues than when they are injected into the blood stream, and as by autoinoculating the patient early, the physician may often "steal a march" on the slow, natural method of "autoinoculation," autotherapy has distinct advantages over even the natural method of cure.

The unmodified toxin complex is therefore the ideal therapeutic agent for treating a patient suffering from any localized and possible non-localized, infectious disease. Furthermore, my unmodified toxin complex therapy has distinct advantages over any form of vaccine therapy for the reason that the unmodified toxins are the parent toxins, or set of toxins, that are in the patient's body, the therapeutic value of which is unchanged or unaltered by the mechanical process of filtration. On the other hand, every step in the process through which a vaccine passes in the laboratory during its preparation, alters or changes its therapeutic effect in the tissues. If a vaccine cures, such cure is due, not to the laboratory manipulation, but in spite of it.

The Therapeutic Action of All Vaccines Is Lowered.—The influence of the culture media on bacterial growth, development, biological and morphological characteristics is beginning to be pretty well understood as new light is thrown on the subject by many investigators. In France it has long been taught that the media upon which bacteria grow, modify the microorganism, both in regard to their biological characteristics, as well as their appearance. Vincent shows that it is possible to make certain non-pathogenic microorganisms pathogenic by simply incubating them on certain culture media, and then vice versa, he may change them back again into non-pathogenic microorganisms by changing back to the culture media upon which they originally grew. This is highly important, from a therapeutic point of view, as showing what grave dangers may lie in the supposedly innocent culture media. Again, one investigator has shown that certain bacteria may be made fermentative or non-fermentative at will, by simply employing certain successive culture media. By a similar process, another shows that certain bacteria may be made gas-producing or non-gas-producing at will. One investigator has gone so far as to state that it is only when bacteria are grown on culture media prescribed by the textbooks, that they behave in the manner the textbooks describe.

There are no conditions under which a microorganism can grow outside of the body that are exactly like those in the patient's body. On the contrary, there are good therapeutic reasons why they should not be so grown, if the best therapeutic effect is to be obtained by their use. There are no accidental or altered toxins from the culture media in my unmodified toxin complex, nor are the morphological or biological characteristics of the infect-

*In this article the writer would appeal to reason and thus awaken professional interest in autotherapy. The strong language he uses is unusual in medical articles; this is an unusual subject. If this article awakens in the mind of the reader a desire to know more of authotherapy and to test the truths herein stated for himself, the author believes he will make a convert of its every reader. There will be no big houses to push the physicians into using autotherapy; only the desire on the part of the physician to cure his patient is the incentive that will cause him to use it. There are many physicians who have this desire. Merely follow the simple technique given and you will have little trouble, and at times be amazed at the cures you will make.

ing microorganisms altered or changed by the simple process of filtration. For these reasons the autotherapeutic remedy individualizes the patient as can no other remedy.

The Therapeutic Value of Filtered Toxins.—The antitoxins of both diphtheria and tetanus are developed in the animal by injecting the filtered toxins of the diphtheria and tetanus bacilli respectively. The antitoxins developed in the animal in response to these filtered toxins tend to combat or antidote any further injection of toxins, they also tend to rout the corresponding microorganism if it is injected into the animal. Developing active immunity in the animal to a given microorganism by injecting the filtered toxins of that microorganism in the healthy tissues, is similar to the development of active immunity in the patient to his own toxins and infecting microorganisms by injecting him with the filtered toxins from his infecting microorganisms. By this process we autoimmunize* the patient to his own infecting microorganisms. Again when the patient is injected into comparatively healthy tissues with the unmodified filtered toxins from the focus of his infection, leucocytes are attracted to the point of injection in large numbers, and they are stimulated by the development of specific antibodies to perform a very definite function—to destroy that microorganism only to whose toxins they responded, the microorganism from which the patient suffers. There being none of these microorganisms at the point of injection, the specific leucocytes pass on into the circulation to the focus of infection, where they combat or rout out that microorganism from the soil of its recent adoption. By no other active immunizing therapy can that organism be attacked so successfully as by the reaction to the unmodified toxin complex developed in the patient by that particular organism, or by the autotherapeutic remedy.

There is no certainty of cure with any heterogeneous toxin or set of toxins, clinical experience for upward of a century clearly proves this. Administering the stock conglomerate vaccines is shot-gun therapy, and empirical prescribing pure and simple, and wholly unscientific.

We believe the two main factors that enter into every infection are, first, the degree of resistance of the tissues, and, second, the degree of virulence of the microorganism to which the patient is exposed. There are no known methods of measuring these two variable factors before an infection takes place, for we are always exposed to a vast number of pathogenic microorganisms and we never know the identity of the microorganism to which we are exposed or that an infection will occur till after it takes place. On the other hand, authotherapy presupposes an existing infection and employs the unmodified toxins of the infecting microorganism to combat that organism. Autotherapy employs Nature's remedy, developed in Nature's laboratory (the body tissues of the patient) for the sole purpose of routing that microorganism.

The danger to the patient and the grave responsibility of the physician in his relation to his patient suffering from an infection of the respiratory tract, has never been so forcibly brought to our attention as the study of authotherapy reveals; for we have never so well understood the direct relation of respiratory infections to so many diseases. Autotherapy makes it very clear that it is but a short step from a "common cold" to many of its lineal descendants, namely, sinus involvement, otitis media, hay fever, asthma, rhinitis, influenza, pneumonia, and many other infections of the deeper structures of the head, chest, and other parts of the body. In chronic infections of the respiratory tract, the resistance of the tissues is often lowered, and the tissues then offer a fertile field for other infections, and air borne contagions; namely, pulmonary tuberculosis, measles, mumps, whooping cough, cerebrospinal meningitis, diphtheria, etc.

In order that it may not be overlooked, the writer will state that in this discussion we are dealing principally with diseases uncomplicated except by bacterial infection. Many bacterial infections, especially those of the nose, pharynx, nasopharynx, larynx, etc., are so closely allied to bacterial infections of other parts of the respiratory tract that from an autotherapeutic point of view it is often unnecessary to make a differential diagnosis to treat them successfully. Ordinary common colds are a mixed bacterial infection, and should be treated as such. This was pointed out by the writer in the *New York Medical Journal*, December 14 and 21, 1912. There the writer states that "acute or subacute bronchitis may usually be cured in twenty-four hours, and a chronic bronchitis is often cured in two weeks by injecting the patient hypodermically with the filtrate from his own sputum at proper intervals."

A physician, who represents the progressive element of the profession and who is therefore a close student of autotherapy, recently remarked as he spit up mucus from a catarrhal condition of the respiratory tract: "There goes my remedy." And he was right! That mucus did contain his remedy, especially fitted or adapted to his individual needs, as could no other. It only needed to be properly filtered, and his remedy, specific for his condition, uncontaminated and unmodified by laboratory technique, would be at hand, ready for use. It could not be exactly duplicated. His condition usually need not be diagnosticated in order that the remedy might cure him properly. In the light of autotherapy, the despised drop of mucus becomes a ministering angel of mercy. It is the priceless heritage bequeathed by provident Nature to cure the patient.

The writer would emphasize that the speed, certainty, and comparative freedom from danger that nearly all acute infections of the respiratory tract may be cured by autotherapy, makes it imperative on the part of the physician to treat the patient, not the disease, autotherapeutically, if he would cure the patient in the quickest and best manner possible and prevent or abort the sequel in the shape of a chronic condition; another infection, a migration of the microorganisms or their toxins to distant parts of the body with coincident pain, increased temperature and results sequel in the shape of indurations, fibrous tissue changes, adhesions, pain, etc. The question arises, if acute inflammations of the respiratory tract or the so-called "common cold" are treated early by autotherapy, may not many of the long category of chronic conditions resulting from infections or contagions above mentioned be aborted? This question is one of great magnitude and importance, and the affirmative answer it appears we are bound to give, opens up therapeutic possibilities that are endless.

In the *American Practitioner*, July, 1913, under

*Autoimmunize is a word the writer has coined to convey his exact meaning.

the title of "Autotherapy—versus Operation," the author reported a case of colicystitis cured, and the operation aborted by injecting the filtrate of sputum hypodermically. Encourged by his success in this, and other similar cases, he employed the filtrate of sputum successfully in two cases of acute appendicitis after operation had been refused, avoiding an operation in each instance. In all of these cases the pain ceased in from six to twelve hours, as if by the action of morphine. It appears that had these cases been operated upon, the cause of the surgical condition would not have been removed, for the surgical operation would have simply removed some of the effects of the infection. The causative microorganisms proliferating in the respiratory tract may again migrate to distant parts of the body and set up constitutional disturbances, such as pain, increased temperature, etc. Autotherapy tends to remove the cause of the disease. It is the condition behind and deeper than the operation that autotherapy often removes. There is no doubt in the writer's mind that by autotherapy many conditions supposedly demanding operative measures may be cured, and the operation avoided.

The writer has employed the filtrate from sputum successfully in many conditions, some of which he could not diagnose. How often have we seen a patient suffering with a toxic disease supposedly foreign to the lungs, die from pneumonia that quickly developed. We are all familiar with this occurrence. The question that engages attention in this connection is that had the bronchial condition been recognized early, and the filtrate from sputum containing the specific microorganism been theraputically employed, might not the life of the patient have been spared? Autotherapy is no theraputic fad or passing fancy, to be discarded in a little while for some other whim method or mode of therapy. The filtrate from sputum will cure a bronchitis in a thousand years from now as well as it does today. Autotherapy is one of the few things that has endured since the earliest period of human existence, and it will endure for all time, for the principal underlying cures made by its use are everlasting and immutable. For this reason autotherapy has come to the physician's hand to stay, and the physician who does not use it in treating patients with localized infections is not employing the greatest weapon we have at our command in fighting disease. We are gradually moving away from complex medication, back to obvious natural therapy. Natural methods may appear crude and simple. The fault is not with Nature, the fault lies in the fact that we have moved so far away from Nature that we fail to appreciate the wonders of her ways. It is because we have not perceived the truths she holds out to us in all of their bearings. This accounts for the endless speculation, controversies, and uncertainty that have characterized the study of medicine through the past ages. Autotherapy marks a new era in medicine. It does not treat the disease empirically in the sense ordinarily understood by the word; it does not give the patient a little symptomatic treatment, or treat the disease locally with modern medicines with high sounding names. Autotherapy treats "the patient" with the remedy Nature designed and foreordained to fit his condition exactly. The wonderful therapeutic value of her preparations cannot be denied.

The patient brings his natural remedy with him to the physician, in his body, and it often can be obtained. Heretofore, we have been imperfectly imitating natural therapy with vaccines. Natural therapy is the conclusion of vaccine therapy. Autotherapy *is* natural therapy.

Antiseptics, oils, and mucous membrane stimulants are at times useful, after the bacterial elements of the blood have destroyed the infecting microorganisms, to assist in the repair of the relaxed condition of the mucous membrane due to the inflammatory condition accompanying the infection, and they at times do cure. Autotherapy, on the other hand, strikes at and removes the cause of the disease, and seldom requires supportive treatment of this nature, except for the physician to have the appearance of "doing something." Local treatment is not contra-indicated as far as the writer knows, except that the local medication should not contaminate the discharge from which the toxins are prepared. The writer believes that all antiseptics as such or preservatives will modify to some extent the delicate enzymes, ferments, etc., that correspond to each bacterial toxin. This is one of the reasons why the toxins should be administered fresh, for the reaction to the unmodified toxins that come out of a patient's body is the exact specific reaction to the same toxins that remain in his body. Another very important reason why the toxin complex should be administered shortly after it is obtained is that if it is kept for several weeks another microorganism may creep into the infected area during the interval, and we would not then expect to obtain the same good results, and we would not then have the additional toxin from the new complicating microorganism and its corresponding tissue toxic substances, as enzymes, ferments, toxic results of chemical changes in the protoplasmic molecule, etc., against which the tissues react in a curative manner as part of our unmodified autogenous toxin complex.

The autogenous vaccines prepared according to the method now in vogue are of altered or lowered therapeutic value. We may not be able to grow the causative microorganism outside of the body tissues. Under these circumstances, the autogenous vaccine of Wright is worthless. It takes time to prepare Wright's autogenous vaccines, while the patient is growing worse. How often have we seen a patient pass the crisis or die while it was being prepared? It is not always convenient or possible to obtain it at the time it is most needed. It requires an extensive laboratory to prepare it. It requires a skilled pathologist, one on whom absolute dependence can be placed. He is not always easy to find. Extraneous matter may creep in during the preparation, and contaminate it, thus rendering the vaccine worthless. The autotherapeutic remedy has none of these objections, for the act of filtering is simplicity itself, and can be done in a very few minutes by any family physician without a laboratory. The physician depends on no one but himself. It is cheap. The merest waif of the city streets is as rich in curative medicine as the millionaire. The remedy the patient needs is always at hand, and can most always be obtained. But the great advantage of my autotherapeutic remedy in addition to the advantages stated above over vaccines is that it contains all of the unmodified toxins from all of the microorganisms and all of the toxic tissue substances that correspond to each bacterial toxin from which the patient suffers. It may be prepared at the bedside wherever the patient may be.

The great therapeutic advantages of the autotherapeutic remedy over Wright autogenous vaccine

are thus apparent, and not open to controversy. The autogenous toxin complex is usually not very toxic. Seldom will the temperature rise above 99° F. The greatest danger is in giving subsequent injections before they are needed. The danger appears to be, not in the use, but in the abuse. This is the danger to which objections may be raised to any therapeutic agent. In its innumerable adjustments our therapeutics of the past resemble in many respects the fashion supplement of some modern trade journals. What is new today is often old tomorrow. Commercialism runs rampant throughout the various ramifications of medicine. Empiricism is at its highest point of development. With the advent of autotherapy, our ideas of medicine have changed, and they will change more as we hark back to Nature and study the beauty and completeness of her ways. If medicine were,

"Content to mark,
And work on the foundation Nature lays,
It would not lack supply of excellence."
(*Dante, Cary's Translation.*)

Therapeutic nihilism must give way to the thought that the purification of the body must come from within. As Christianity teaches, for spiritual defects, the cure must come from within, so autotherapy teaches for physical defects the cure must come from within. Autotherapy is the religion of the body. Self-therapy, or self-preservation is the fundamental principle of life. It is Nature's first law. Nature is the "true healer," the physician her servant. The history of medicine is largely the history of false gods that have been worshipped, of false doctrines that have been expounded, of medical money changers that compete in their efforts to defile God's holy temple—the human body. Their wares too often contravene and block the "true healer," Nature, in her efforts at restoration. With the advent of autotherapy, the patient will not so often have to be satisfied with a diagnosis of his disease, and then simply wait, not for the physician, but for death to relieve him. Today and tomorrow, and the day after tomorrow, are the days of therapy, principally autotherapy. Therapeutic nihilism and therapeutic agnosticism must give way to autotherapy. With the advent of autotherapy, the family physician again comes into his own. He rarely now has to send his patient suffering with an infectious disease to "highly specialized" specialists. By its use the family physician can more often treat his patients suffering with an infection of the ear, nose, throat, chest, stomach, abdomen, pelvis, and a vast number of other organs, and at the same time, be quite sure the patient is getting the remedy fitted or adapted to his individual needs, and no other. Autoimmunizing the patient to his own infecting microorganisms is being employed successfully by hundreds of physicians, in every state in the Union, and in many other parts of the world. Old Dame Nature is the pharmacist supreme. An unalterable trust may be reposed in her therapeutic preparation.

The writer knows full well that the tendency of physicians of today is to accept nothing but that has been developed in the laboratory. The fundamental basal principle that underlies the cures made with the autotherapeutic remedy is that it be unmodified in the laboratory. Demonstrated results should not be despised nor ignored because they do not seem to coincide with the doctrines or theories of men who may be temporarily in exalted positions, and who assume the rôle of virtuous infallibility.

Many of us who have lived but a short time in medicine have outlived the creed of too many who have arrogantly assumed that everything outside of their own little private flower bed was incredible and impossible. Until we know all possible changes that can transpire in complex organic chemistry and biology, it is becoming that we be more humble and broadminded. "Indifference to demonstrated results is an intolerable attitude," *Journal American Medical Association.* Meltzer says in the *Journal American Medical Association*, "Men trained exclusively in the laboratory do not seem to see that a medical fact observed critically by a capable physician deserves as much credence and consideration as a fact developed by laboratory methods. The laboratory man offers positive opinions in a field in which he has had no experience." Hippocrates insists that "observation rather than speculation is the true instrument of progress." In the last analysis the ultimate object of all laboratory investigation is therapy. Autotherapy is the keystone in the arch of the great medical superstructure that has been raised by both dominant schools of medicine. As the keystone fills out the arch joining the two leaning sides, so autotherapy joins the two great schools of medicine by strengthening and beautifying each, for this is Nature's method of curing the patient. Autotherapy is the medical "tie that binds" our hearts in therapeutic faith.

The formula given below will often have to be altered somewhat to suit the individual needs of the patient. The following technique was closely followed: Sputum, 1 dram; distilled water, 1 ounce. Mix in a two-ounce bottle, shake well, and allow to stand for twenty-four hours. Filter through a Berkefeld filter. Inject twenty minims of the bacteria-free filtrate into the loose cellular tissues over the biceps muscle. Give no further dose until the patient ceases to improve under the preceding dose. In chronic cases this will often be from the third to the fifth day, although the condition of the patient should always be the guide as to the time when another dose is needed. In very weak patients, and in very chronic cases, proportionately less should be given. One injection will, however, usually cure an acute or subacute bronchitis within twenty-four hours.

There are various modifications of this treatment that are at times useful, but the therapeutic value of none of these has been proved to be greater than that given above. For example, the writer uses the following method in treating desperate cases in which it is necessary to hurry medication. This method is used also when it is impossible to see the patient again. It is useful mainly because it saves time. The time between obtaining the sputum and giving the injection may be shortened by thoroughly grinding a dram of sputum in a mortar with powdered glass, or with fine sharp clean sand previous to mixing with water. When this is done the mixture should be thoroughly agitated in the bottle to dissolve the soluble toxins. When the microorganisms are destroyed, their toxins go into solution by autolysis, the fluid is then filtered through a Berkefeld filter, and twenty minims of the bacteria-free filtrate are injected at once. The writer has found it impossible to make the toxin complex for bronchitis too toxic by following the formula and precautions given above. The formula is well within safe limits. For this reason it is recommended that it be given in increasing doses until there is a slight systemic effect manifested between this and the next dose.

After the chill, it is often unnecessary to give another, but to make assurance doubly sure the writer gives another. Always make enough of the filtrate to last after the sputum has dried up, and the patient has been almost cured. In chronic cases the writer uses the same filtrate for three or four doses. Do not allow the sputum and water to stand longer than twenty-four hours before filtering, for the filtrate then becomes exceedingly toxic.

Pulmonary tuberculosis requires a very special autotherapeutic technique. The following cases have been selected from hundreds of others cured in a similar manner that might be reported:

CASE I.—Acute Bronchitis.—Dr. ALEXANDER VERTES of Louisville, Ky., reports the following: "Patient, male; age 9 years; had a bronchitis for ten days. There was a dull pain in the chest under the sternum and a painful cough that came in spasms, but one injection relieved the pain in twelve hours. He made a rapid and uneventful recovery. I am using autotherapy when it is applicable to the exclusion of all other medication, because it gives me results that no other medication has ever given." An acute congestive bronchitis usually has "a crisis" or resolution which sets in within twenty-four hours after the first injection.

CASE II.—Dr. FENNER, of Sacramento, Cal., reports the following: "Patient, Mrs. M. A. F., age 67 years, on November 24, 1913, took to her bed with a hard cold and congestion of the lungs. I prepared the Duncan unmodified toxins from her sputum and gave her the following doses: November 27 I gave her a hypodermic injection in the left arm. There was a light local and constitutional reaction. About twenty-four hours after the injection the cough stopped and the excretion was much less. By the third day the excretion had stopped. I gave her two other injections on December 2 and 10 for good measure. There has been no return of the symptoms, although she is subject to chronic catarrh of the throat and bowels. She claims the treatment stopped a noise in the ears that had been present for many years." Autotherapy appeals to me more strongly than any of the serums or vaccine therapies heretofore advanced." The sore throat of singers and public speakers usually responds quickly to this treatment.

CASE III.—The following letter appeared in the *New York Medical Journal*, November 1, 1913. It is self-explanatory:

"LOS ANGELES, CAL.,
"2915 South Vernon Avenue,
"October 13, 1913.

"To the Editor:—In the December 14 and 21, 1912 issue of the *New York Medical Journal*, Dr. Charles H. Duncan published an article under the title of autotherapy. In this article he stated he was able to cure acute and subacute bronchitis within twenty-four hours, and a chronic bronchitis within two weeks. I determined to try it on myself first as a patient. My father had bronchitis for forty years, and I have had it for many years. I am now 54 years old. The chief symptom in my case is severe coughing spells almost every night. These usually lasted from half an hour to forty-five minutes. I mixed one part of sputum with five parts of water and allowed it to stand for twenty-four hours, with occasional agitation, and then filtered it through a Berkefeld Filter. I had Dr. Carl Johnson, of Los Angeles, give me an injection in the lumbar region. I coughed none the night following. The second night I coughed five minutes. On the third day I had another injection. I have had four injections altogether, each four days apart. My bronchitis has been cured or aborted for I now cough none. The only symptom I have at present, if it can be called a symptom, is on rare occasions there is a slight effort at coughing, wholly unlike my previous cough. I can truly say it has been magical.

"I do not know Dr. Duncan. I never heard of him before I read his article, and I merely write this that others who are similarly afflicted may know of this grand treatment. I shall try autotherapy out in all of its various phases.

"L. C. TONEY, M.D."

CASE IV.—Patient, female; age, 23 years; occupation, school teacher, has had a catarrhal condition of the nose and throat since she was 8 years old, when she had scarlet fever. She had running ears for several years afterwards.

She has never been free from a catarrhal condition since. In recent years she has been subject to recurrent bronchitis. She would scarcely get over one attack before she would come down with another. The present attack came on September 21, 1913. When first seen on the 28th she had a deep cough which caused great pain under the sternum.

She did not have to give up her school duties but attended to them with difficulty. She coughed practically all night for the past week.

On September 30 she was given an injection of the autogenous toxin complex made from her sputum. The pain in the chest left within twenty-four hours. She coughed none the night after the injection. On October 6 there was a return of the pain in the chest and a slight cough, but she could scarcely raise enough sputum from which to prepare her toxin complex. On October 7 she was given another injection. This cleared up the whole condition quickly.

CASE V.—Chronic Bronchitis.—Patient, male; age 52 years, had a catarrhal condition of the nose and throat for the past two years. During the past six months he has had difficulty in concentrating his mind on his business. Would go half to sleep when talking business. Was drowsy and apathetic and his sexual powers were markedly diminished. He came for treatment for his mental condition. It was then that the catarrhal condition above mentioned was discovered. He did not complain of spitting mucus in the morning. This was learned during the examination. He was given an injection of the autogenous toxin complex prepared from the sputum. After the third he had a chill, and all of his symptoms disappeared and have remained absent now over two years. No other medication was given.

Hundreds of remarkable cases treated successfully both by the writer and other physicians might have been reported but space forbids. Professor Wm. H. Freeman says: "After ten months' experience in using filtered sputum hypodermatically in chronic bronchial affections especially chronic phthisis, I am convinced this is one of the great therapeutic advances of the age. Dr. Duncan's autogenous toxin complex is the most scientific vaccine ever used in medicine."

CASE VI.—Acute influenza or La Grippe.—Dr. F. B. BORROWS of Plainwell, Michigan, reports the following case of influenza treated by him: "Patient, Mrs. T. M., had an influenzal infection of both ears. Rupture occurred on the fourth day after the attack. On the eighth day I placed some of the discharge from the ears in some water, about two ounces, let it stand for twenty-four hours, at the end of which time I filtered it, through the Duncan autotherapeutic apparatus and injected twenty minims of the filtrate subcutaneously. A moderate reaction followed. In five days I repeated the process, which was followed by a complete cessation of the discharge from both ears. There was some sense of fullness and distention in the ears for a few days after, but a complete recovery followed. I have been using autotherapy in my practice now for over a year with great satisfaction; in all kinds of localized infections, almost invariably with success."

CASE VII.—Influenza or La Grippe.—Patient, Dr. Warren B. Rush of Lake City, Florida; age 64 years. The patient had been suffering with an influenzal infection of the larynx since 1893. During this interval he had several acute exacerbations that threatened his life and at other intervals he was unable to attend to his practice. The infecting organism was diagnosed microscopically many times during this period as the influenza bacillus. He has long suffered with pain in the joints, and often when the temperature was only 50° F. he was not able to leave the house on account of suffering from the cold. After an acute exacerbation during July, 1913, he came to New York and placed himself in my hands for autotherapeutic treatment. The following report is in the words of the Doctor himself: "On August 10, 1913, I went to New York City and placed myself under the care of Dr. Duncan. August 11 I received my first injection of the filtrate from sputum. Between this time and September 20, 1913, I received five other injections, and thanks to the skilful administration of his autogenous toxins

I am a well man today, September 25, 1913. The microorganisms in the sputum grew gradually less and less after each injection. After the fifth none could be found. I made these microscopical examinations myself at the New York Post Graduate Medical College and Hospital where I had gone to take a course in pathology for the express purpose of learning how to diagnose my infecting organisms. The pain and coldness have entirely disappeared. Since beginning this treatment I have gained ten pounds in weight, and feel better than I have felt in years. I am glad to give Dr. Duncan credit for this grand cure. Autotherapy has done for me what apparently no other medication could do. It means that my usefulness in life has been restored. March 14, 1914, there has been no return."

CASE VIII.—Otitis Media.—Dr. Bardes of Newnan, Georgia, reports the following case: "Patient, female; age four years had suppurative otitis media for three years and ozena for quite a while, all very offensive to the smell. February 25, 1913, I made the Duncan toxin complex from cotton saturated with the excretion from the nose and ears. I gave five minims hypodermatically. The suppuration lessened and the improvement was marked and progressive for about eight weeks. It then appeared to come to a standstill. The suppuration had ceased from the nose and one ear, and the odor was very slight. May 15 I gave five minims of fresh unmodified toxin complex in the same manner. The patient went right along to recovery, and is well and as fat as a pig."

CASE IX.—Dr. C. E. Fenner of Sacramento, Cal., reports the following case: "G. E. F., male; age 34 years, had an old chronic catarrhal otitis media, coupled with nasal and pharyngeal catarrh. The hearing gradually became dull during the summer of 1910. It became very much worse from December, 1911, to November, 1912. At the end of this time he could not hear his watch at all. Average tone conversation could not be heard. In October I received your autotherapeutic apparatus, No. 1, and prepared the Duncan toxin complex from the excretions from the nose and ear and gave him an injection on the following dates: November 1, 4, 10, 18 and 29. November 29, injection given. December 10, 15, and 27, and January 2, 9, 17, 30. At this later date I had difficulty in obtaining enough excretion from which to prepare the filtrate. The most severe reaction was after the injection given November 29. Cutaneous reaction was seven by three inches. Temperature, 102°. Immediately after this injection the patient could hear a small clock in the office. He then steadily improved and can now hear preaching. The discharge from the ear stopped after the fifth injection. I consider this case most remarkable, as nearly everything known to medical science had been done for the patient previously without relief."

CASE X.—Dr. Fenner's case: "Patient, male, age, 9 months; weak and sickly; never played or laughed; appetite, poor; digestion, poor; frequent bowel disorders; cried constantly; chronic bronchitis. December 8, 1913, he was suffering with an extremely severe cold on both lungs and in the head. The ears had been running pus and serum for several weeks, but my being called was on account of a large abscess in the right parotid gland about the size of a small orange. Right cervical glands enlarged and very hard. There was a scaly strumous area over the right ear and occipital region. There were also several large ulcerous spots scattered over the face. I instructed the mother to catch on cotton and save all the excretion from the ears, nose, and throat during the next fifteen hours. Just twenty-one hours afterwards I gave the first dose of the Duncan toxin complex of three minims hypodermically. Forty-eight hours afterwards five minims were given. There was a strong local and fair systemic reaction. In seventy-two hours after the first dose the discharge from the ears stopped. The excretion from the nose had nearly stopped. The swelling of the parotid was almost normal in size and only one cervical gland was enlarged. The child coughed but little. In five days the whole condition cleared up except some râles in the bronchial tubes, and shadow spots under the skin where the ulcer spots had been. One week later the child began to laugh and play with the other children of the family, a thing he had never done before. I gave two more doses of five minims to be certain of no return of the condition January 14. The father said: 'Doctor, that medicine you gave my baby certainly did wonders for him. I can almost see him grow. He is getting to be a healthy child."

CASE XI.—Sinus involvement.—Dr. Francis E. Park of Stoneham, Mass., reports the following case: "Abscess of the frontal sinus. Marked inflammation was present and supposed the cavity would have to be opened. I made a Duncan toxin complex from the pus and injected twenty minims of the filtrate hypodermically. There was marked relief following this. I gave two other injections, but the case was cured by the time the last was given." Dr. Park says further: "You have given the medical profession another weapon of great power against disease."

CASE XIII.—Pleurisy with effusion.—Dr. Borrows's case. "Mr. M. came to me in April, 1913, saying that during the previous October he had an attack of pleurisy and that he had apparently recovered. Beginning March 5 he had night sweats for three weeks and wanted to know why. Upon examination I found an effusion of the pleura up to the fifth rib. I withdrew thirty minims of the fluid and injected it under the shoulder subcutaneously. He reported forty-eight hours afterwards with no fluid. Five punctures failed to find any."

CASE XIII.—Hay fever and asthma.—Dr. M. L. Curtner, of Vincennes, Indiana, reports the following case treated by him: "Patient B. M. had hay fever and asthma for ten years. I prepared the Duncan toxin complex and injected one cubic centimeter intermuscularly, every second day for four doses. This stopped all symptoms and they have not recurred now nine months later.

I have treated three cases of otitis media by your method with good results. One case of lobar pneumonia with immediate and excellent results."

CASE XIV.—Dr. C. A. Sturtevant of Manchester, N. H., reports the following case treated by him: "Patient female, age 68 years, suffered with bronchitis and asthma for years. The only relief she could get was by taking some patent medicine containing cocaine. She spit up almost a pint of mucus every morning, which was thick and albuminous. I prepared the Dr. Duncan toxin complex from her sputum and injected twenty minims subcutaneously. Her cough was relieved in a day or two, and apparently cured within a week or ten days. She had no other medication."

CASE XV.—Dr. Sturtevant. "Patient female, age 60 years, has suffered with bronchitis and asthma all her life. She has an associated valvular regurgitation, intermittent with dilatation. I gave her an injection of your autogenous toxin complex prepared from the sputum. Immediately following the injection there was some cyanosis and labored breathing with palpitation, which lasted for an hour or so. I did not see her again for two weeks; at this time she said her cough was practically cured."

Dr. Sturtevant says further: "I have treated many other infections with autotherapy with equally good results."

Caution—Be sure the case is a true asthma. In acute asthma and hay fever autotherapy appears to be the specific. Many chronic cases are readily cured. Many hay fever cases require an operation before they can be permanently cured. Autotherapy is not supposed to cure when surgical operation is demanded. Autotherapy merely raises the bacterial elements of the blood to overcome the infecting microorganism."

CASE XVI.—Ozena.—Dr. Rierson of Dixon, California: Patient "G. D. V., cement worker. Ozena and chronic bronchitis of years standing. Breath so foul he would be avoided by people talking to him. There was also a pterygum on the left eye. Treated with sputum according to the Duncan method April 25, 1913, and three other injections four days apart with a cure of the ozena and bronchitis. The pterygum was diminished two-thirds in size. After this an injection was given occasionally. The patient was satisfied with the treatment. Dr. Rierson says further: "In all I have treated more than one hundred and ten cases with autotherapy; boils, rheumatism, infections, etc., with results that have been a revelation to me, and to my patients. Eight cases out of ten so treated were cured; this included those who would not allow me to finish the treatment. Sometimes we have patients to deal with like this. I believe autotherapy has a great future and that it will relieve more suffering than anything else that has come before the medical profession.

CASE XVII.—Tonsillitis.—Dr. R. L. Rierson, of Dixon, California: "F. C. Autotherapy. One dose.

Cured. The writer has had no failures when this infection is treated early, and he has treated many."

CASE XVIII.—Pneumonia.—Patient, male, age 54 years, had a chill January 12 at six o'clock P. M. That night he had painful and difficult breathing accompanied by headache. When seen by the writer the next morning he had a temperature of 103° F., pulse 120. There was consolidation over the middle lobe of the right lung. His face was flushed. A dram of bloody sputum was placed in a mortar and thoroughly ground with powdered glass. It was then mixed in a bottle with an ounce of distilled water. It was thoroughly shaken and allowed to stand for half an hour. It was then filtered through a Berkefeld filter, and two hours after obtaining the sputum he was injected with twenty minims of the filtrate. In six hours the temperature dropped to 98° F. and the pain ceased, so that he breathed easy. He was weak and remained in bed for several days longer. He progressively but slowly improved and at the end of two weeks he left the house. He has been well now two years.

CASE XIX.—Patient, female, age 45 years, was under autotherapeutic treatment for acne vulgaris by the writer. In the early part of May, 1913, she called and said that while in the subway a few minutes before she had had a severe chill. There was great pain in breathing. She had the characteristic pneumonia grunt. Temperature 103° F. A little blood-streaked sputum was raised with much difficulty, accompanied by great stabbing pains. There was consolidation over the middle lobe of the right lung. Her face was flushed and she was evidently very weak. A dram of sputum was obtained while in the office, and within two hours she was given a hypodermic injection of the filtrate. Two hours later she breathed much easier and the next morning the temperature was normal, but the patient was weak. In forty-eight hours after the first injection she was given another, of the same filtrate. In four days after the initial chill she was up and around the house but still a little weak. She made an uneventful recovery.

The mortality from pneumonia has been much greater in New York City during the past few months than that from pulmonary tuberculosis. It is imperative that these cases be treated early if the best results are to be obtained. When given within twelve or twenty-four hours after the initial chill, autotherapy appears to be the specific for pneumonia. Space alone forbids me giving a number of most interesting cases treated successfully by the writer and by many other physicians. The veterinary physicians are unanimous in vouching for the specificity of autotherapy. Their leading men say it would be a crime not to give it to horses. It may be interesting to note the simple technique they employ successfully in treating animals suffering from pneumonia: Mix the exudate and water (they employ the prune juice discharge from the nose of the horse). Boil it for five minutes. Filter through a sterile bandage or cloth and inject the filtrate hypodermically.

CASE XX.—Cholecystitis.—Patient, Mrs. N., age forty-five years, was first seen by the writer December 11, 1911, suffering from an inflammation of the gall-bladder. Under the usual treatment she alternately improved and relapsed several times during the following year. Jan. 21, 1913, she became very much worse. Her condition pointed unmistakably to pus in the gall bladder. She had pain over the region of the gall-bladder that extended to the back; the least movement even talking or deep breathing causing severe pain. She vomited at seven o'clock on the morning of the 21st, and at eleven o'clock P. M. she had a chill. The next day Dr. George F. Laidlaw was called in consultation to see the case. He diagnosed the case as cholecystitis, the same diagnosis the writer had previously made. He recommended an operation within forty-eight hours. The writer elicited the further fact that the patient had been suffering from a catarrhal condition of the respiratory tract, the beginning of which coincided with the pain in the region of the gall-bladder. Autotherapy of bronchitis and catarrhal conditions of the respiratory tract having previously been so successful in the hands of the writer, it was decided to make a test of this case and see whether the treatment of the catarrh with the filtrate from the sputum would have any effect on the condition of the gall-bladder. Accordingly 4 c.c. of the sputum were placed in an ounce of distilled water, and allowed to stand for twenty-four hours with occasional agitation after which time it was filtered. On January 22 at 10 o'clock P. M. 20 minims were injected hypodermatically into the loose cellular tissue over the biceps muscle. The next day she reported that within ten minutes after the injection the pain became very much worse and continued to be very severe until 3 o'clock A. M., after which time she went to sleep, and did not wake till seven o'clock the next morning. When seen the next day the patient was comfortable, though there was still some soreness in the region of the previous pain. She gradually improved however, and did not have another pain for two weeks. These pains were dull aching in character but not as sharp or severe as they were before. However the patient was frightened and feared the old trouble was returning. Another injection of the same filtrate was given when the pain again disappeared within a few hours. The injections were then repeated every five days as long as the catarrhal condition lasted, that is till March 20. She has not had any pain since the second injection, which is now about three months. At this time the patient had gained seven pounds in weight, and can now eat food which was restricted during the greater part of the past year. She rides in an automobile which had given her distress during the past six months. On March she reported she had no more catarrhal symptoms. The sputum had been gradually diminishing since the first injection. The patient was discharged on this day but told to return if she had any more pain or if the catarrhal condition returned. Six weeks she came to the office in response to a telephone call but a physical examination did not reveal any soreness or tenderness over the seat of the former pain. She said she was in good health and she apparently was. April 24, 1914: No return of the pain.

CASE XXI.—Dr. Fenner of Sacramento, Cal. Miss O. H., age 29 years, had been treated by three other doctors and in several institutions for three years. She complained of spasmodic recurring pain in the stomach and the region of the gall-bladder. After a careful examination and an analysis of the stool by the city laboratory I diagnosed the case as catarrh of the bile duct and bowels. After I had given my diagnosis she said that this was the diagnosis of three other physicians who had been treating her. I prepared the Duncan autogenous toxin complex from the stool and the excretion from the nose combined and gave the following doses. Nov. 26, 1913, minims five. Hypodermically. Local slight, systemic slight. She was given six others about six days apart. At the end of this time she was greatly improved. She had no pain and could eat most anything. February 27 she said she was better than she had been for a great while although she had been under a great mental strain (nothing to do with the disease) she could eat and had been eating at hotels. She got wet twice in the rain and took no cold nor had she any return of the old trouble."

If the physician treats catarrhal conditions of the respiratory tract autotherapeutically, he will often be surprised to discover that he has cured conditions supposed to be remote from the lungs.

CASE XXII.—Acute appendicitis.—Patient, male, age 35 years. Both his lodge and family physician pronounced his condition as acute appendicitis, and recommended an immediate operation which was refused. The writer not knowing their diagnosis also pronounced it appendicitis. Operation was still refused. In questioning the patient it was discovered that he had a catarrhal condition of the respiratory tract. A dram of sputum was obtained and in three hours he was injected with the unmodified toxin complex. In six hours all pain disappeared. He was given two more injections. He went to work in a week later. Three months later he had a return of the pain. He was then operated upon. The appendix was found to be full of pus with many adhesions over the abdomen. He had been subject to recurrent attacks of these pains for several years. He was then treated autotherapeutically with the pus from the wound and made a rapid recovery. The writer, being a surgeon, knows how difficult it often is to accurately determine the exact condition of the abdomen before it is entered, and for this reason he believes that every case of acute appendicitis should be operated

upon. He cites these cases mainly to show what can be expected of autotherapy in treating those patients who refuse operation.

CASE XXIII.—Patient, male, age 65 years. The diagnosis of acute appendicitis was made by his family physician, and he was referred to a surgeon. He did not like the surgeon and applied to the writer, whom he knew. He believed he would die if he was operated upon and refused operation. He was given an injection of his toxin complex made from thick sputum five hours afterwards. In six hours after the injection the pain left as if by the action of morphine. He was given five subsequent injections four days apart. There has been no return now nearly a year.

CASE XXIV.—Postoperative treatment.—Patient, male, age 60 years, fell from a ladder breaking his left arm and straining the ligaments of the left groin, with severe bruises over the shoulder, head, and legs. The abdomen was tender and the pain from an old inguinal hernia was intensified. A bronchitis he had previous to the fall became aggravated and within forty-eight hours he complained principally of severe pain incident to coughing. A drahm of sputum was placed in an ounce of water and allowed to stand for twenty-four hours with occasional agitation, at the end of which time it was filtered and twenty minims of the filtrate were injected into the loose cellular tissues over the biceps muscle. In two hours he felt better and stopped complaining. In twenty-four hours his coughing ceased entirely.

It appears from this and similar cases that a bronchitis or coughing spells following an operation may often be benefited or cured quickly by this simple treatment. There are normally myriads of pathogenic microorganisms in the lungs. When the vitality of the patient is lowered for any reason, as after an operation, or where there is irritation in the lungs due to the anesthesia or other cause, these microorganisms tend to proliferate and a true bronchitis or infection of the lungs will tend to develop.

Pulmonary Tuberculosis.—Incipient cases of pulmonary tuberculosis appear to respond well to the filtrate of sputum in the manner suggested, except that the interval between injections should usually be somewhat longer; at times they will not need another injection for from four weeks to three months. Advanced cases require the toxins from the complicating microorganisms before they require the tuberculous toxin. In order to get rid of the tuberculous toxin from the toxin complex, the writer makes a culture from the sputum on media upon which the tubercle bacillus will not grow. The toxin complex minus the tuberculous toxin is then prepared in the usual manner, *i.e.* the mixture of microorganisms and water is allowed to stand for twenty-four hours with occasional agitation, after which time it is filtered. This filtrate may then be injected very much more frequently than the filtrate prepared in the usual manner. Some advanced cases treated in this manner appear to improve when they did not improve on the repeated injections of the filtrate of sputum prepared in the usual manner.

233 LEXINGTON AVENUE.

A SKETCH OF THE ORIGIN OF AUSCULTATION AND PERCUSSION AND OF THE STATE OF CLINICAL MEDICINE IN THE TIME OF AUENBRUGGER AND LAËNNEC.*

BY RICHARD COLE NEWTON, M.D.,

MONTCLAIR, N. J.

PRESIDENT NEW JERSEY STATE BOARD OF HEALTH; CONSULTING PHYSICIAN, MOUNTAINSIDE HOSPITAL.

IT is related of a margrave of Baden that he fell ill in Heidelberg some time about the middle of the 17th century and summoned his physician-in-ordinary, who, accompanied by two distinguished consultants, proceeded to render what aid he could to the titled sufferer. After due deliberation it was determined to apply a plaster over the patient's heart, when a dispute arose as to whether the human heart lies in the middle of the chest, as Galen had taught, or upon the left side. To settle this controversy a pig was brought in and its chest opened before the eyes of the noble patient, who perceiving that the animal's heart lay on the left side of its chest concluded that his own was also on the left side (Baas, Hist. of Med., p. 556). This led him to dismiss his family physician and incidentally to disregard the teachings of Galen, an act requiring no inconsiderable courage in a layman or a physician two or three centuries ago.

The simple device of applying the ear to the chest to determine the location of the heart never seemed to have occurred to these disputants, any more than it occurred to the learned savants, in the incident related by Chisholm, to weigh the vessel and the fish separately and together, instead of spending hours in bitter controversy over the question whether a vessel of water would gain weight or not by putting a fish into it. The conclusion arrived at was that a live fish would not increase the weight of the vessel but a dead one would. As Karsner (Lect. on Rise of Experimental Med., Mch. 13) observes, this was philosophy. A long while afterwards some skeptic actually settled the question to his own satisfaction by weighing the vessel under

*Read before the American Climatological Association, June 20, 1914.

the different conditions specified. This was science.

Laënnec says that it is very singular that the passage in Hippocrates's works—in which the latter states that by applying his ear to the chest he could tell whether, if it contained fluid, this was pus or water, "seems never to have engaged the attention of physicians and there is no evidence that his experiment has ever been repeated until the present (*i.e.* Laënnec's) time." (a period of over 2000 years.) Yet he continues: "I had myself read this passage of Hippocrates many years before I entertained the idea of mediate auscultation." He then points out that it is remarkable that the great Hippocrates himself did not pursue this method of research further but adds rather sententiously "Yet nothing is of more common occurrence. It is not given to any man to comprehend all the relations and all the consequences of the most simple fact; and we know that nature's secrets are more frequently betrayed by fortuitous circumstances than obtained by the force of our scientific efforts." (P. 29 Dis. of Chest., Forbes's translation.)

Whether Hippocrates really practiced percussion or not seems quite doubtful; although Elliott claims that he did. (P. 20 Outlines of Greek and Roman Hist., 1914.) It appears also that he did paracentesis for fluid in the chest and recognized the fact that the fluid should be withdrawn gradually to prevent syncope. Baas asserts (p. 644 Hist. of Med.) that the Salernean physicians practised auscultation in the diagnosis of tympanites and ascites. But adds that "a diagnosis of the diseases of the great viscera had never been attempted in this way until finally Auenbrugger independently brought to light an ingenious use of the ear" which made possible a diagnosis of diseases of the chest and abdomen entirely unattainable before his time.

Auenbrugger was a nobleman of Auenbrugg, Germany. He was born in Graz in Styria in 1722 and died in 1809. He studied the humanities and philosophy in his native city and medicine in Vienna, where after graduation he practiced medicine for several years. In 1751 he was placed in charge of the Spanish Military Hospital and the hospital of the Holy Trinity in Vienna; where, for a time at least, he labored gratuitously, devoting himself assiduously to clinical study and observation. He was quite a musician and a friend of the arts. His musical ear, quite probably, was a great aid to him in devising the scheme of auscultation which has brought him posthumous fame. He practiced it for seven years in the Spanish Hospital before publishing the results of his labor in 1761. The style of percussion that he practiced was immediate, no pleximeter being used. He struck the chest gently with the points of the fingers brought together and stretched out straight and then flexed; the patient holding his breath; a a muffled sound or one of higher pitch than usual indicating the presumable site of disease. He insisted that either the percusser should wear gloves or that the chest should be covered with at least one thickness of cloth. This proviso was probably necessary in immediate percussion. (Garrison, p. 282.) This great discovery which seems simple enough to us, was slighted and opposed by de Haen, Sprengel and other contemporaries. The two named were, of course, eminent men, and the former especially prided himself upon his diagnostic acumen. In 1803, forty years after Auenbrugger had published his "Inventum Novum." Sprengel wrote "It is scarcely credible that he (Auenbrugger) could have diagnosed any disease of the lungs and thorax by means of the resonance," and for that matter a well-known medical writer, who died in 1861, who produced the standard translation of the works of Hippocrates and other learned and valuable medical works, is said never to have admitted the possibility of detecting the sounds of the fœtal heart by auscultation. In 1803 the great Frenchman, Corvisart, revived this forgotten and neglected discovery by translating Auenbrugger's treatise and commending it highly to his students, after he had himself tested it in his practice for a number of years. He is said to have become Napoleon's regular medical adviser partly because he practiced percussion, which struck the Emperor as a method of diagnosis of a careful and painstaking man. Corvisart's generous treatment of Auenbrugger shows his honorable and high-minded nature. After translating the treatise on percussion he gave all the credit for its discovery to Auenbrugger, although he might easily have claimed it for himself. He says with fine feeling that he would not sacrifice the name of Auenbrugger to personal vanity, adding, "It is he and the beautiful invention which of right belongs to him that I wish to recall to life" (Garrison, p. 283). Of Auenbrugger, Garrison says that "he is indeed a noble example of the substantial worth and charm of old-fashioned German character at its very best."

Laënnec was descended from a respectable family in the little city of Quimper in Bretagne. He was born in February, 1781, and died of consumption in 1826. His early education was neglected owing to poverty and other causes, although his uncle, who had charge of him, was "one of the first physicians of Nantes and a man in every way distinguished" (Baas, p. 1012). Instead of sending the boy to school he took his nephew to camps and hospitals, where this feeble lad laid the foundation of his future brilliant career as a clinician. In fact the schools in France were closed for a long time during the Reign of Terror, and yet young Laënnec, like other brilliant men in history, seemed rather benefited than otherwise by the lack of routine schooling. At nineteen he went to Paris where he so amply made up for lost time, in his education, that he acquired sufficient mastery of Latin and Greek to be able to write well in both languages. As Baas says, a rare qualification in a modern Frenchman. His medical studies also received the most zealous attention. After having published a number of valuable medical papers he made in the year 1815, in the Société de l'Ecole, his first experiments with the stethoscope. His original instrument was a block of wood about ten inches long and four inches in diameter with a central canal and at the thoracic end an obturator, upon which Laënnec himself laid great stress. According to his own account (Dis. of Chest, p. 6) he had been in the habit of making use of immediate auscultation "for a long time in obscure cases and where it was practicable." Hence we see that both auscultation and percussion, one or both, had been practiced, at least occasionally for thirty or forty years before Laënnec discovered the stethoscope. This happened accidentally in 1816, when he "was consulted by a young woman laboring under the general symptoms of diseased heart, and in whose case percussion and the application of the hand" (to the chest wall) "were of little avail on account of the great degree of fatness. The other method

(immediate auscultation), just mentioned, being rendered inadmissible, by the age and sex of the patient," he "rolled a quire of paper into a kind of cylinder," and used it as a stethoscope. The result pleased him so greatly that from that moment he imagined "that this instrument might furnish means for enabling us to ascertain the character, not only of the action of the heart, but of every species of sound produced by the motion of all the thoracic viscera." He found upon trial that "the hollow cylinder is essential for exploration of the voice," while a solid one is best for examination of the heart. After various experiments he concluded that wood was the best material out of which to make these stethoscopes. I can remember seeing our honored ex-president, Dr. Beverly Robinson, use a small billet of wood for a stethoscope, which resembled the sawed-off top of a bed post. This was 35 or 36 years ago, when he was a visiting physician, and I was an interne in the old City Hospital in New York. I presume that Dr. Robinson, who had studied in Paris, had brought this instrument from there. I remember that he told me that he preferred this old-fashioned stethoscope to the modern binaural instrument.

However the limits of this paper will preclude a study of the various styles of stethoscopes, a field which has been well covered by Dr. D. S. Lamb in a paper read before the Medical Society of the District of Columbia April, 1910.

In the pursuit of his studies, in wise counsel and sound instruction, Laënnec had the advantage of studying under Corvisart, and was a contemporary of Louis, Pinel, Andral, Piorry, Rayer, Ricord, Bretonneau and Bouillard, a truly extraordinary galaxy of brilliant internists, who were quick to seize upon and exploit Laënnec's great invention. These, together with Depuytren, Larry and Cuvier, probably touched the high-water mark of the French influence in medicine, and gave an impulse to the development of correct diagnostic methods and the careful study of pathological anatomy which is even now felt in the advance of medicine. America was especially fortunate, because such men as Holmes, Gerhard, the Jacksons, the Shattucks and other American physicians were pupils of the great Louis and of Laënnec and Corvisart, and were students in Paris in the period just mentioned. Garrison says (p. 343, Hist. of Med.), "The strong stand which Louis took in favor of facts and figures, as against the sterile theorizing of the past, appealed especially to the keen, practical common sense of these northern physicians" who were afterward prominent among the founders of American medicine.

Had Auenbrugger been as fortunately placed in Vienna as Laënnec was in Paris, he probably would not have died feeling that his long years of labor in the Spanish Hospital, carried on as he himself said "*inter labores et tædia*," had gone for naught. It was the noble-minded Corvisart that introduced Auenbrugger to his own countrymen, and it was a pupil in Corvisart's clinic named Bayle who is said to have been the first person who studied the heart's action by applying his ear to the bare chest wall. It is stated that Corvisart himself never did this, although he admitted that he had heard the pulsations of the heart several times by listening very close to the chest. Just how close, we are not informed.

It all seems wonderful to us. The slow development of natural, scientific medicine is hardly comprehensible to our modern intelligence and practical way of looking at things. But we must remember that there was really nothing scientific about mediæval medicine. It was a curious mixture of metaphysics, superstition and dogma learned by rote and supported by "authority." There were practically no dissections for over a thousand years after Galen. In fact, this great medical light was obliged to do his dissecting on animals, and, in justice to his memory, some of the anatomical mistakes in his writings must be acknowledged to be the unavoidable consequences of this fact.

Galen is said to have considered himself extremely fortunate in having been able to see and study a human skeleton. Baas says that the University of Vienna did not acquire a skeleton until 1658. Strassburg, in 1671, obtained a skeleton of a man and several years later one of a woman. About 1725 the great Haller was obliged to flee for his life from Leyden, because he had been engaged in grave robbing to secure material for dissection.

It might be said that Paracelsus was the Luther of medicine. When he declared in the early part of the 16th century that all diseases are parasitical, he started the emancipation of the human mind from the idea that all disease was either a divine or a diabolic visitation. It was, however, over two centuries after this before instruments of precision began to be used in the study of the human body, in health and disease, and about the same time the belief in the sacredness or accursedness of the human corpse had become sufficiently modified so that dissections might be more commonly made, and finally so that practical anatomy could be insisted upon as a part of the regular course of study for the degree of doctor of medicine.

Boerhaave was using a clinical thermometer in the first quarter of the 18th century, and was the first to use a magnifying lens in studying the eye. John Floyer (1649-1734) was the first man to count the pulse by the use of the minute watch. This was a watch which ran for exactly one minute, with which Floyer made many observations on the human pulse in health and disease. He was followed in this study by Haller. Floyer tabulated his results, but his work was neglected or vitiated by a revival of the old Galenic doctrine of "specific pulses," *i.e.* "a special pulse for every disease." However, Louis also adopted a minute watch to count pulses and by his great influence succeeded in rendering it popular.

All these mechanical aids to diagnosis were at first scoffed at and derided and finally furiously adopted. Skoda in Vienna studied every case that came along with the most minute refinement of physical diagnosis, without apparently caring a fig for the patient's welfare. It is said that he either would not prescribe any treatment or would only do this in the most perfunctory manner.

After Floyer, according to Weir Mitchell, "observation went minutely mad (furnishing) a whole Lilliput of symptoms, an exasperating waste of human intelligence." And so it goes as Hecker has so wisely remarked "physicians seem to be condemned to the fate of rarely discovering the golden *via media* of truth between the by-paths of error."

This cursory review of the state of clinical medicine when auscultation and percussion were introduced is to my mind most refreshing, inasmuch as it gives us at least a glimpse of a widespread and substantial advance in the development of the heal-

ing art, whose great importance we can scarcely overestimate. One very obvious benefit is that the adoption of this method of study has done a great deal to shake the nonsense and superstition out of medicine, by making us observe and watch the human body in its minutest detail as well as en masse. It has advanced the practical side of physiology and therapeutics and paved the way for its own great successor in the march of medical knowledge, which now holds the stage, and promises great things for the future in addition to great things already accomplished. I refer, of course, to bacteriology and the study of natural and acquired immunity and prophylaxis, in short of preventive medicine. Our study has afforded us a pleasant aspect of a rational and substantial movement in medicine, and offers a delightful contrast to the involved, complex and often ridiculous systems of the pedants and philosophers, who have tried to measure out art with the tiny yardsticks of their own restricted intellects and have succeeded about as well as the theologians and scoliasts have succeeded in measuring the infinite.

42 Church Street.

PUBLIC HEALTH EDUCATION

By HORACE GREELEY, M.D.,

BROOKLYN, NEW YORK.

It is very fortunate for the race that the individual may not indefinitely prolong his existence else those habits and prejudices which fasten so securely upon the majority would be a serious hindrance to human progress. The Struldbrugs encountered by Dean Swift's Gulliver were not such a nuisance as we would undoubtedly prove ten generations hence to our advanced descendants. Of course, this is the result of that molding which produces the adult from the child and which is absolutely essential for the purposes of each generation—for some general idea or belief, true or false, of everything and every question met is a prerequisite for even that elemental self confidence which prompts a man to venture beyond his own door step. This locating, or, as Kipling says, "finding," of one's self is the first thing that any conscious being does, and is followed by similar explanation of all that strikes his senses. Of course the accuracy of each interpretation depends upon intelligence as determined by hereditary nervous system construction and the individual experience, education, previously had. However, accurate or inaccurate, such whys and wherefores soon become entrenched by habit, till finally "meetin' houses aint sotter," and dislodgment of even the most absurd conceptions becomes extremely difficult.

To teach an old dog a new trick has, until quite recently, been thought easy as compared to instilling into the adult public modern ideas of hygiene and sanitation. But anyone who has lived around New York for the past five or ten years cannot have helped noticing the marked change that has taken place in the public's attitude toward unnecessary exposure and handling of food stuffs, common drinking vessels, kissing the baby, ventilation, and promiscuous expectoration. Intelligent understanding of these and allied questions has spread so extensively that it is not mere enthusiasm that would lead one to think that before many more years are passed sanitary knowledge will be so universal, and applied so thoroughly, as to make the care of the passing population part of the customary routine, and to permit time and attention to be given to the great work in eugenics which lies ahead, but in connection with which ground has not yet been broken, despite the many meetings and discussions we hear of, for the welkin echoes to other sounds and the welfare of those next to come is hardly yet at heart, certainly not at hand.

But to the purpose in hand, what remains to be done? First and foremost to take measures for the further spread of such information as will provide guiding lines along which the public may safely reason in regard to all matters affecting them in health and in disease. "There's a reason" may be good food in an "ad," but the "real stuff" is demanded by a discriminating digestion and alone can have definite and permanent effect. Therefore, first and foremost, in all primary schools, at least one year before the law permits a child to leave, such physiology and hygiene, including the principles of communicable disease, should be taught as will afford unshakable foundation for all after thought on health and disease. Not the routine trivialities that are now run over in the schools, but the actual addition, multiplication, division, and subtraction of human biology. At least as much time as is now devoted to mathematics will be required, but why not? Self-preservation is the first essential and such proper knowledge is equally necessary for the good of others. To teach what may be called abstract education, such as history, language, and even mathematics, while neglecting the self-preservation essentials, is as reprehensible and foolish as the attempt of the famous philosophers of Laputa to build a house from the roof downward. Mental gymnastics are good but why not let them deal with matters which will nourish and preserve that which we are striving to develop, and no one has ever claimed that it was undesirable to kill two birds with one stone!

Of course, as sanitary science has barely compiled its primer, we could not have expected the public previously to have had anything but the most chaotic and most nonsensical ideas on the subject. Now, however, introductory notions are at least well established, and these, for the good and for the protection of all, should be pressed home; through the schools first and then through the public press. The latter, although in need of almost as much instruction in matters of health and disease as the average citizen, is a sine qua non to the success of the undertaking. We may teach child or adult to complete knowledge and conviction, but unless constant reminders and examples are exhibited throughout life, practice will not follow principle, or at least will be soon neglected. Even should school instruction in such matters never be forgotten nor disregarded by individuals progress in knowledge will demand that constant additions be made to the public sanitary information storehouse, which in the case of the adult public can alone be reached through the newspapers. Here the first thing to do is to stop the mills of false and misleading information whose products are so flagrantly spread over our dailies. In such matters the newspaper man has heretofore thought, not are the statements real and true, but are they interesting and striking, sensational, no doubt never pausing to think—not knowing himself even —the harm which indirectly results from such publications in obscuring, and even in denying, real facts whose realization constitutes the forewarning necessary to all forearming.

Several years ago, in preparing an article

(Newspaper Medicine, *L. I. Med. Journal*, April, 1909), I looked over the issues of the four principal New York dailies during a period of three months tabulating the articles, news and other, on medical and sanitary subjects, and found that some 94 per cent. of all were in error as to some essential fact. Of what may be called magazine-section articles all, 100 per cent., were grossly false or misleading. I communicated these findings to the respective proprietors of the journals with the suggestion that a medical, or at least a scientific, editor would obviate recurrences of such errors, but the most encouraging reply received was that "We are not yet prepared to make such an innovation, especially since the real good to be accomplished thereby does not seem to us to be great." It therefore behooves our public sanitary authorities to show these men how from unwitting befoggers of the public sanitary sense they can become chief agents in its enlightenment and future progress.

Newspaper co-operation is absolutely essential for the necessary iteration and reiteration of basic principles, and for the proper presentation of those daily events which so profusely supply those object lessons so necessary to carry conviction into action, where extra exertion and inconvenience confront an otherwise willing convert.

Lectures are of no value and are really obsolete, since anything that is worth learning cannot be acquired by our average citizen from an average speaker in even 100 times the time which would be required to impart such information through print. No one attends a lecture that does not read a newspaper—very few indeed can be dragged thereto under any circumstances—and the cost of the former method of instruction would be infinitely greater. That which is printed can be read over again, but of that which has escaped even a golden tongue hardly more is caught by the listener than the penult of the peroration, to which even Echo awakes.

Sight, besides being our most necessary and important sense, is that least easily fatigued and is the avenue by which the most information in the least time can reach our nerve centers. This is one of the reasons why the moving-picture theater shows have become so popular, as the strain of attention is immensely less than when the drift of the events must be largely gathered by the ear. Consequently, as a medium of public health education, such shows can be of great public service, especially to particular classes, and to the youth who so largely patronize them.

With the public health authorities as a controlling, stimulating and guiding agency what rapid progress could be made in this self-protection teaching! With an active campaign where would quack medicine and genito-urinary advertising "specialists" be at the end of a year! The drug trade might suffer a diminution of sales, and even old-time "shot-gun" prescribers might experience a change of heart. One of the greatest benefits which will accrue from this public health education work is that the populace will learn to know when medical attention is required, and last but not least will be enabled to judge intelligently of a physician's merits and services rendered. At present it seems that some people call physicians as a matter of routine while others no matter how serious the event delay medical consultation as long as possible.

In the food line the saffron could soon be "educated out" of butter, and part, at least, of the husk be restored to our staple cereals. A slight conception of the physiology of digestion and of the relation thereto of the common food stuffs will more markedly than anything else affect public practice, even as regards the consumption of alcoholics.

The old time principles were to make laws and to enforce them, but since Peter the Great forcibly seized his nobles and cut their obnoxious beards, such methods of reform have diminished both in favor and in practicability till to-day, at least in most matters of health and sanitation, the slogan is, Give us the reason and we will use it!

With the rise in importance of the "carrier," and of cases of acute infections with masked symptoms, as the causes of the spread of communicable disease, and experience in vain attempts to rid individuals of such dangerous seed, the value of education in bacteriological knowledge has greatly increased as it seems to be the sole protection against these foci of infection which are undoubtedly very numerous among us. In this connection prophylactic education will meet with great difficulties; for instance, how hard it will be to prevent the carrying of unwashed hands to mouths and noses! Let anyone doubting this try by an attempt at self-practice for even three hours and he will learn. People are becoming crudely educated in regard to the subtleties of dust, but ask my lady or her escort before luncheon, "Do you wish to wash your hands?" and you will be rewarded with "Oh, no, I washed them just before I went out," and even the removal of the loose dirt that, upon his return from school, Johnnie wipes upon the towel diminishes germ possibilities about as much as the drowning of the first pigeon reduced the census of Noah's Ark. Of course careful hand washing may be said to be only essential when the hand has had direct contact with an actual source of disease, but it is so thoroughly neglected generally that, even at medical meetings, one may observe that very few think of it before proceeding to the table. "What the eye doesn't see the heart doesn't grieve for," will certainly continue to be the rule until the basic principles of microbic disease are thoroughly imbued in the public mind. How can one expect laymen to intelligently observe quarantine regulations if they be ignorant of the whys and wherefores? No wonder a physician was told the other day by the wife of his consumptive patient, when he protested against expectoration upon the floor, "Never mind, doctor, I always rub it under my foot this way to kill the germs."

Another way of teaching the public is through the physician, for no one else is in such a position to carry conviction on such matters to a patient or to a patient's family as he. However, he has so little time, apart from direct professional duties, that much of this work would be impossible unless he were provided with printed leaflets on such subjects. Such pamphlets distributed with the physician's approval and endorsement would be invaluable in every department of public health education work.

The greatest bugbear of the statesmen of the last century was the uneducated proletariat, with which, in this, public sanitarians will have to deal, for it is it which bears the "bugs." Indeed many triumphs of preventive medicine await this health education work, for to stay the sower's hand is far easier than to pick up the seed!

140 Clinton Street.

THE USEFUL SURGEON.

By H. W. WIGHTMAN, M.D.,

OMAHA, NEB.

PROFESSOR OF ANATOMY AND CLINICAL ANATOMY CREIGHTON UNIVERSITY, MEDICAL DEPARTMENT.

In the great commercial organizations merit and fitness are the accepted qualifications for leaders. Men who have demonstrated ability in certain lines are chosen to lead, and important work is trusted to their care. One regrets to say that such conditions do not universally exist in the medical profession. It appears that the public in general, is absolutely in ignorance in so far as the selection of a useful surgeon is concerned. The great majority of people are of the opinion that all physicians are likewise surgeons, and competent to perform all forms of surgical operations. It is this belief and confidence of the layman that encourages many physicians untrained in surgery, to make attempts to perform major operations, usually with deplorable results. We do hope that the time is close at hand when the public will be safeguarded against this blundersome surgery. We must congratulate the American College of Surgeons for the step they have taken, which will, in the course of a few years, put surgical work in the hands of those capable of doing beneficial work. The members of the A. C. of S. are selected on account of a hign standard of excellence in surgical work—men who, by virtue of their positions, will shape the destinies of the future professional standards.

The surgeon who has acquired knowledge by years of study and watchful experience, who has the energy to keep up with all modern advances, and who possesses the ability to impart knowledge to others, is the man fitted for the occupancy of the highest position in the surgical field.

The teacher of surgery must be more than a mere operator. The progressive surgeon must be a man of good health, tireless energy, temperate habits and rigid honesty, with a courage based upon an accumulated knowledge which can be drawn upon in emergencies and difficulties. He must possess a power of decision based upon care and observation, in placing at their true value the results of the research of others, promptly seizing and applying discoveries of merit, but never going to the extent of dangerous radicalism. He must be able to make correct deductions from histories of patients to conclusively advise the indicated treatment and prognose the probable results. He must constantly aim to achieve distinction and fame, acknowledge the qualities of thoroughness and patience, be rapid and correct in thought and have in him the true fire of genius. He must be an accurate diagnostician and use careful judgment in deciding as to the advisability of operating and as to what particular method should be pursued; he must, moreover, be prepared to meet the many emergencies which inevitably arise during an operation and which demand prompt and decisive action, oftentimes modifying the opinion formed beforehand.

The fundamentals of the practice of good surgery are anatomy, physiology, and pathology, and without these one is handicapped in progress.

All of our great surgeons and teachers of surgery are also competent anatomists and pathologists. Descriptive and practical anatomy is the ground work; living anatomy is what we deal with in the patient, and a clear knowledge of pathological anatomy enables one to correctly interpret deviations from the normal, and to intelligently forecast the probable course and prognosis of the surgical affection. With the proper qualifications a surgeon sees clearly the important aspects of the case, and knows how to present them to the student distinctly and impressively.

Proficiency in surgery cannot be obtained by operative experience, not by assisting one versed only in the elementary mechanics of operative surgery. The great surgeons use their heads more than their hands.

To become a useful surgeon the candidate, after graduation, should spend at least eighteen months as an interne in a hospital having a well-trained and organized attending staff. The hospital training should cover general medicine and surgery, including their subdivisions, and a course in anesthetics must not be neglected. The hospital training forms the nucleus for the further development in either medicine or surgery, or the specialties. After completing the interneship one should serve as assistant to a surgeon of known ability, devoting a reasonable amount of time assisting at operations. Assisting more than three hours daily in actual operative work deprives the assistant of too much energy, for he must devote study to the patient, case histories, reviewing the surgical literature, and devoting not less than two hours each day to laboratory anatomy and pathology. Six hours weekly should be given to experimental surgery upon animals, chiefly for the purpose of gaining dexterity in making incisions, applying hemostats, acquiring speed in ligating blood vessels, tying knots, doing neat and rapid suturing, and practicing the various operations of the gastrointestinal tract, especially with reference to accurate and rapid suturing. Finally, whenever the opportunity presents, he should perform all the various operations on the human cadaver.

After having operated on not less than fifty dogs, with a record of good postoperative results, the assistant can then be trusted with some minor human surgery, preferably under the guidance of his master. At least two and one-half years should be served with a surgeon of recognized ability, before attempting unguided major operations on the human subject.

He should spend at least one month every year seeing other surgeons work, and not less than two hours each day with journals and books. Not having time for such devotions is a remark often heard from operators, and it is simply expressing their lack of progressiveness. Our greatest and busiest surgeons will never tell you that they have no time for observation, reading and teaching. It is to this work and interest through many years that their success is due. Many of our operators are busy the greater part of the day, but upon investigating how their time is occupied, one finds that it is spent for the most part in doing only minor surgical work which should be turned over to an assistant, thus helping to educate him and to encourage him to advancement. This courtesy and interest a surgeon owes to his assistant, who perhaps for many years has served him most faithfully. It is the duty of every leader in medicine to develop at least one successor among his pupils who can eventually take the place of the master.

A modern surgeon each day must call to his aid a knowledge of anatomy and pathology, the only foundation upon which a surgical education can be built. What manner of man is he who is so lost to

conscience that he would dare attempt to remove a goiter or mass of lymphatic glands from the neck, a gallstone from the common duct, or a carcinomatous uterus from the pelvis without having acquired an accurate knowledge of the anatomical relations of these parts?

The surgeon of today must acknowledge due conservatism, and contraindications and limitations of operations. Conservative surgery justifies the hope that anatomical and functional regeneration may take place. He must pride himself on being conservative with the knife, yet acknowledge the valuable discoveries made by a daring knife. A conservative surgeon when in doubt as to the technique or outcome of a special operation will first acquaint himself with the anatomic relations by a study and application of the method in the cadaver, or on lower animals and thus reduce the risk to human life and conserve the interest of his patient. Days of discouragement must come to every surgeon, but it is through his unsuccessful efforts that he may learn to temper his ambition by the judgment that comes from experience. He must be ready to recognize his own deficiencies and possess the courage and determination to overcome and correct these deficiencies. We often hear of the so-called brilliant operator who, to the astonishment of an audience, removes a carcinoma of the mammary gland in ten and one-half minutes. Every surgeon of experience knows that malignant growths require a most painstaking dissection of the neighboring tissues, that the removal be as near complete as careful and extensive dissection can accomplish. The element of time in an operation for the removal of malignant tissue is scarcely to be considered. The conscientious surgeon considers the thoroughness of the operation, not his brilliant speed; speedy, incomplete operations are pitiful for the cause of surgery and the interests of the patient are not conserved. The possession of mere operative ability, no matter how brilliant, unless this is combined with other qualifications of a surgeon will be apt to make a dangerous rather than a useful surgeon.

Clinical experience alone will not make a competent surgeon unless he takes the time to thoroughly investigate each case as to the cause and pathological conditions involved, applies recognized methods of treatment and follows the results of his treatment. Too often we find that the so-called surgeon has an extensive practice and he does not take the time required for the proper care and study of cases. However, he gets along mechanically through much operative work, but of what use is such a man to progress, and to the ultimate results of his case? Of what use is he as a teacher of medical students, to the development of proficiency in himself or his assistants? He should let his assistants do the minor and routine work, while he devotes himself to the real progress of surgery.

The best teachers always and invariably practice on a basis of thorough knowledge of contemporaneous achievements in surgery and do not shun discussions of dubious points in professional gatherings. Mutual discussions and discoveries are very important elements in the advancement of surgery. The modern surgeon immediately reports both successful and unsuccessful operations along new lines calling for the comments and criticisms of other surgeons.

815 Park Avenue.

HERPES ZOSTER AND MALARIA.

By WILLIAM H. DEADERICK, M.D.,

HOT SPRINGS, ARKANSAS.

PHYSICIAN TO THE LEO N. LEVY MEMORIAL HOSPITAL.

The recognition of malaria as an etiologic factor in herpes zoster is not recent. Besides its mention in the standard text books on dermatology writers on tropical diseases have noticed the relation.

Crespin[1] states that the thoracic form is most frequent in malaria. Dantec[2] mentions the associations of zoster and malaria. In 1780 cases of malaria Anders[3] found one hundred and eighty-nine instances in which complications occurred, herpes zoster appearing once. Masson[4] observed a case of zoster following the course of the sciatic nerve. In another the right half of the face was attacked. Moursou[4] cites several similar cases. Girard[5] encountered a case following intercostal neuralgia of malarial origin. Thayer and Hewetson[6] observed zoster once in six hundred and sixteen cases of malaria in Baltimore. Colombini, Donnell, Riesman, and Powell[7] adduce personal observations in support of the malarial origin of zoster.

The most careful study of this subject is that of Winfield[8] who reports thirty-three cases of herpes zoster in which the parasites of malaria were found in eighteen cases. In only two of these cases is the form of the parasite specified: the estivo-autumnal.

I give below brief notes of eight cases which have occurred in my experience.

Case I.—C. B., white, male, age 13, seen July 8, 1906. His previous history is negative. On the morning of June 27, 1906, he had a typical malarial paroxysm followed by fever which lasted twenty-four hours. During the night of the 27th and the morning of the 28th he took four or five three-grain doses of quinine. He has had no further chills, but has had fever several times: During a paroxysm a pain began in the left side and the next morning herpetic vesicles appeared, extending from the level of the eleventh dorsal vertebra to the median line in front above the umbilicus. The spleen extends an inch and a half beyond the costal margin. The temperature is 99°, the pulse 98, and the feces negative for ova of intestinal parasites. The hemoglobin is 75 per cent. and a few estivo-autumnal rings are found.

Case II.—J. A. L., white, male, age 35, occupation laborer, seen July 17, 1907. He began to have chills in July, 1906, and had them until April, 1907. During this time the longest interval free from chills was a week. Five days ago a pain began in the right side and two days later the eruption appeared, and extends from the vertebrae to the sternum at the level of the fourth rib. The spleen is not palpable, the temperature is 99.8°, the feces are negative for ova. The hemoglobin is 70 per cent. and occasional estivo-autumnal rings are present.

Case III.—B. P., colored, male, age 64, occupation farmer, seen July 18, 1907. He has had no manifestations of malaria since the past fall. July 10, while plowing he was struck with the plow handle just over the crest of the right ilium in the posterior axiliary line and the next day was similarly injured just above the anterior superior spinous process on the same side. July 13 the eruption began at the site of the first injury and now extends from the vertebra column to the median line in front, being more intense at the point of the first injury. The temperature is normal and the blood is negative for parasites. He has taken no quinine recently.

Case IV.—G. G., colored, male, aged 72, occupation farmer, first seen August 21, 1907. He gives no history of malaria for twelve years. Ten days ago he was taken with a pain down the anterolateral aspect of the right thigh, four days later the herpetic eruption appeared in this area. The spleen is not enlarged, the temperature is 100°, he has had no quinine recently and the blood is negative for malaria.

Case V.—S. P., white, female, age 21, seen December

24, 1907. She had typhoid fever three years ago and has been having chills irregularly since September, 1907, the last one two weeks ago. She has taken no quinine since then. Four days ago a pain began in the right side and the next day the eruption appeared. It extends from the vertebral column to the midsternal line crossing the seventh interspace in the mammary line. The temperature is 99.8°, the hemoglobin 90 per cent., and the blood examination shows a very few estivo-autumnal rings.

Case VI.—G. W., colored, female, age 40, a cook, seen March 2, 1908. She has had a fibroid tumor of the uterus for nine years. She gives no history of malaria. During the past several months she has complained of pain in both shoulders, three weeks ago a pain settled in the right arm and two nights ago the vesicles appeared on the outer aspect of the right arm from the shoulder to a little below the elbow. The temperature is normal, the hemoglobin 95 per cent., and the blood examination shows no parasites. She has taken no quinine recently.

Case VII.—L. L., colored, male, age 40, a farmer seen July 10, 1908. He had a number of chills during the past summer and fall. About a week ago a pain began in the left side and three days later the herpetic eruption appeared. It extends from the vertebral column to the sternum at the sixth interspace. The temperature is 100.2°, the hemoglobin is 90 per cent., and the examination of the blood shows estivo-autumnal ring bodies.

Case VIII.—B. J., colored, male, age 15, a farmer's son, seen July 27, 1908. He had pneumonia when a young child and has had malaria nearly every summer. On July 19, he noticed a burning upon the right side of the forehead and next day of the upper eyelid. July 20, the eruption began upon the right upper eyelid and rapidly extended over the entire right side of the forehead from the median line back to two inches beyond the hair line. The right eye is closed and the lashes are glued with pus. The conjunctiva is red. The temperature is 100.6° and the blood shows numerous estivo-autumnal rings.

Of the above eight cases five were colored and three white.

Five of the cases were associated with malarial infection, of whom two were colored and three white.

The form of the parasite in all cases was the estivoautumnal.

The greater per cent. of the infection found in whites in this small series is in keeping with the relative immunity of the negro to simple herpes and many other complications of malaria.

Thickening of the Palate and Upper Part of the Larynx, Probably Due to Congenital Syphilis.—H. Lambert Lack reports three cases that showed diffuse thickening of the uvula, pillars of the fauces, and adjacent parts of the soft palate, and of the epiglottis, arytenoids, and upper part of the larynx. The condition was chronic and did not yield to treatment by idodides, or mercury, or salvarsan. It was apparently stationary or varied very little, and showed no tendency to ulcerate. There was occasionally slight difficulty in breathing.The cases were similar to two others the author had previously shown, about which differences of opinion had arisen. In all but one the Wassermann reaction had been positive, and the diagnosis of congenital syphilis rested entirely upon this. In none of the cases had any treatment been beneficial, nor had microscopical sections of portions of tissue removed thrown any definite light upon the pathology.—*Proceedings of the Royal Society of Medicine.*

CEREBRAL SYPHILIS IN THE SECONDARY STAGE.

By C. BURNS CRAIG, M.D.,
NEW YORK.
CHIEF OF CLINIC, FIRST DIVISION, NEUROLOGICAL INSTITUTE.

The importance of recognizing that syphilis may attack the cerebrospinal axis early in the course of the disease cannot be overestimated. The general practitioner, the dermatologist and the genitourinary specialist probably see more curable cases of syphilis of the nervous system than a neurologist. Until we have substantiating evidence, we cannot assume that there are different strains of the *Spirochæta pallida*, one or more having a predilection for the nervous system, however true this may be. We should rather err on the safe side and hold that when the spirochete has once invaded the body it is liable to attack the nervous system. The clinical stage of cerebrospinal syphilis is usually late and were the initial, secondary and tolerant periods energetically and vigorously treated the nervous system would never suffer.

Fortunately, however, the clinical stage of cerebrospinal syphilis is not always late. Even before the induration of the chancre has disappeared and while the rash is in a florid state, the central nervous system may be the site of attack. This is more fortunate than otherwise as symptoms arising from involvement of the nervous system are usually regarded more seriously by the patient, and treatment is less apt to cease by default. The character of the lesion in the nervous system at this stage of the disease is usually meningitis, and the commonest resultant symptom is headache, although root symptoms, cranial, or spinal may occur. The following case is illustrative of the group in which the former symptom—headache—alone is indicative of an active inflammatory state in the meninges.

Case I.—A construction contractor 35 years old complained of a "splitting headache," so severe that sleep for the past week had been practically impossible. The pain was confined chiefly to the frontal and temple regions. He had had a sore throat three months ago which lasted three weeks. A generalized rash and shooting pains in the legs developed about the same time. Ten years previously he had had a phagadenic ulcer on the penis which disappeared after a few weeks' treatment locally with a "yellow powder." During the past two months he received 1/32 gr. of bichloride of mercury and 10 grs. of potassium iodide, four times a day without appreciable diminution in symptoms.

On examination a dark reddish papulosquamous rash with whitish or yellowish crusts was seen to be symmetrically distributed over the face, back, and extremities including the palms. The pupil and tendon reflexes were normally active. Examination of the eyes including fundi revealed nothing unusual. Station was secure and the physical condition was otherwise negative. Cerebrospinal fluid contained 150 lymphocytes and an excess of globulin, and there was a positive Wassermann reaction. This reaction was also plus in the serum.

He was given neosalvarsan 0.9 gm. intravenously. During the succeeding 48 hours the headache gradually subsided and disappeared. A week later he received a similar dose; two weeks later another. At this time there was only the faintest suggestion of light pinkish macules over the body and there had been no return of head pains. After disappearing from observation for eight months he returned, not because of any symptoms, but to be "on the safe side." At this time the Wassermann reaction in both fluids was negative; there were 20 lymphocytes in the cerebrospinal fluid and no globulin excess.

The rapidity with which the head pains disappeared in this case bears ample testimony to the potency of neosalvarsan in cerebral meningitis in the so-called secondary stage of syphilis. This case

and the succeeding similar one make pertinent the advisability of examining the cerebrospinal fluid in all cases of syphilis with eruptions of the skin and mucous membranes.

The following case serves to represent the second group of such cases in which root symptoms as well as headache are also present.

Case II.—A foundry-man aged 28 years had been suffering for six weeks with pain in the right side of the head, extending down the same side of the neck almost to the shoulder, and also along the outer border of the ear. During his seven years of married life, he had twice indulged in illicit intercourse; two and a half years ago and six months ago; on the latter occasion with a prostitute. One month afterward or five months ago he noticed a small indurated chancre on the penis for which nothing was done. He was never ill in his life and is the father of five healthy children.

Examination revealed a reddish macular rash distributed symmetrically over the trunk and extremities and the tonsils showed herpetic patches. In the coronal sulcus of the penis was a whitish scar the size of a grain of corn, the skin surface of which was apparently healed, but induration was still present. Aside from a well marked dorsal kyphosis the physical examination was negative. There was no ocular disturbance, the pupils were equal, regular in outline and promptly responsive to light. The tendon jerks were normally active, no tremor was manifest and there was no difficulty in station or gait. The Wassermann reaction was plus in the serum and negative in the cerebrospinal fluid. The latter fluid contained an excess of globulin and 130 lymphocytes per c.mm.

Four successive treatments of salvarsan 0.6 gr. intravenously rendered the Wassermann reaction negative, caused the globulin excess to disappear and reduced lymphocytes to 15. His pains disappeared after the first treatment and have not returned

While the treatment of general paresis and advanced tabes is rather disheartening, the promptness and completeness with which such cases of cerebrospinal syphilis as these responded to arsenical therapy is very gratifying. The powerful action of salvarsan and neosalvarsan upon the inflammatory process in the brain and meninges as exhibited in the improvement of the symptoms and the condition of the cerebrospinal fluid is significant. That the syphilitic progress has been arrested is certain. That the spirochetes in direct contact with the blood stream as it permeates the tissues have been destroyed is probable. That all spirochetes have been killed is an open question and only time and future observations can decide. Such cases as those described above should certainly be kept under observation with repeated serological examinations for years to come.

37 West Fifty-fourth Street.

DETECTION OF GELATIN IN ICE-CREAM.

By DAVID I. MACHT, A.B., M.D.,

BALTIMORE, MD.

Enormous quantities of ice-cream are consumed in the United States every day. Even an untrained mind after a moment's deliberation will suspect that the greater part of this cream sold at such low prices as the ice-cream sodas, sundaes, or plain ice-cream, in the stores "around the corner," cannot consist of pure cream—in other words, it is adulterated.

What substances are used in making up the chief commercial ice-cream on the market? Besides milk and eggs, the following substances chiefly have been used to adulterate ice-creams: corn-starch, gelatin, gums, and agar-agar.

In the present work I have investigated a large number of samples of ice-cream for the presence of gelatin. This may be of interest, for several reasons; in the first place, because it is well to know what we are putting into our stomachs; secondly, gelatin, though possessing some nutrient value, cannot take the place of pure cream; and thirdly, some people, as for instance orthodox Hebrews, regard such ice-creams as not kosher and prohibited by the Jewish dietary laws.

To detect gelatin in cream or other foods is not an easy problem, as it is difficult to distinguish that substance from other proteids. It is necessary first to precipitate entirely all proteid bodies, for if any are left and are tested for gelatin, the two will be confused with each other.

I have experimented a good deal on the subject and have found the method given by the English chemist, A. W. Stokes (*Analyst*, London, 1897, Vol. XXII, page 320) the most satisfactory and convenient for the purpose.

Two reagents are prepared:

No. I. Dissolve pure metallic mercury in twice its weight of strong fuming nitric acid (Sp. g. 1.42). Dilute the solution with 25 volumes of water.

No. II. A saturated aqueous solution of picric acid.

To test for gelatin, take 10 c.c. of the cream or substance to be tested and add 10 c.c. of reagent No. 1. Add 20 c.c. of distilled water. Shake vigorously for three minutes and let stand for five minutes; then filter. If much gelatin is present it will be impossible to get a clear filtrate, but it will be more or less translucent. But the positive test for gelatin is as follows: To a portion of the filtrate (3 to 5 c.c.) add an equal volume of reagent No. II. If gelatin is present, a yellow precipitate will *at once* be formed, within 30 seconds. If no gelatin is present the solution will remain perfectly clear yellow.

I have practised the above described method on mixtures of gelatin and water, mixtures of gelatin and milk, and mixtures of gelatin and cream. The test is very delicate indeed for all practical purposes, as it will be positively given by one part of gelatin in 10,000. When the reagents are ready on hand the whole test can be performed in 10 minutes and in the cold.

I have examined specimens of all ice-creams available in the market, and was surprised to find that almost all the commercial or cheap ice-creams give a positive reaction, and that in abundance, thus pointing to the presence of gelatin. That substance was found absent only in the highest grades of ice-cream made by confectioners and sold at 50 or 60 cents per quart. Another curious fact noted was that contrary to my expectations starch is but very little used in thickening of ice-creams. The presence of starch is, of course, very easily determined by the iodine test.

3218 Auchentoroly Terrace.

Congenital Defect, Sixth and Seventh Cranial Nerves.—E. B. Smith reports the case of a male aged 3 years who was brought for weakness of one side of the face. This defect had been noticed since the second week of life. Delivery was moderately easy and no instruments were used. There was complete seventh nerve paralysis on the right side and also paralysis of the external rectus on the same side. The condition suggested a congenital defect of the sixth and seventh cranial nerves.—*Proceedings of the Royal Society of Medicine.*

A NEW DEVICE IN TRACHEOTOMY.

IN spite of the fact that American experience has demonstrated the superiority of intubation over tracheotomy in the relief of acute stenosis of the larynx, the latter operation is still the one chosen by preference almost invariably throughout Europe. In a recent brochure on this subject Guillermo Zorraquin* of Buenos Ayres, cites statistics which to his mind prove that the mortality following intubation is greater than that following tracheotomy. He refers to the greater technical difficulties of intubation, the fact that in some instances it not only fails to relieve the laryngeal obstruction but actually changes a dyspnea into an asphyxia, and that it may change an acute obstruction into a chronic one causing through traumatism the formation of cicatricial tissue. For these reasons he inclines to the operation not as a last resort but as a routine procedure in the treatment of acute diphtheritic stenosis of the larynx. For this purpose he has contrived a special type of tracheal cannula which he believes favors the physiological conditions present in respiration and the pathological state of the larynx.

Zorraquin studied experimentally the effect of laryngeal stenosis upon the character of the respiration. For this purpose he induced stricture of the larynx in dogs by means of applications of sulphuric acid or ammonia, and then recorded by means of the graphic method the resulting changes in the respiratory curve. He notes from the study of these changes that the dyspnea is always and solely inspiratory. The graphic traces show that the inspiratory phase is more prolonged and difficult than normally, while the expiratory phase is shorter and more rapid than normally. Following each respiration there is a pause whose duration is proportional to the degree of obstruction. In seeking to explain these changes the author notes that the lungs are accustomed to perform their function under an atmospheric pressure that is normal or greater than normal. The increased pressure is produced by the play of the vocal cords, as during the production of the voice or of a cough. In the normal larynx there are other factors that tend to accentuate the differences between inspiration and expiration. During the latter the position of the vocal cords like the "beak of a flute" and the pressure of the expired air facilitate the opening of the glottis. These conditions are exactly the reverse in inspiration, and the inspiratory phenomena are still more accentuated during the course of stenosis of the larynx.

The author next studied the character of the respiratory curve in individuals wearing an intubation tube or a tracheal cannula. He found that in the former the respiratory movements are more frequent and ample than normally, giving evidence of a greater muscular effort. These conditions are even more marked in cases that have been tracheotomized. Zorraquin attributed these changes to the reduced tension of air in the pulmonary alveoli and to the lessened diffusion of the residual air, both of which favor atelectasis and bronchopneumonia. The problem which he next sought to solve was how to establish in cases of stenosis of the larynx the normal condition of respiration; in other words, how to restore free inspiration and at the same time to maintain the positive pressure of the alveolar air during expiration. These problems Zorraquin believes he has solved in the invention of a tracheotomy tube provided with an adjustable orifice guarded by a lamella of mica which gives free ingress to the air during inspiration, but tends to obstruct it during expiration. This compels the patient to inspire through the tracheotomy tube and to expire through the larynx. Traces taken with this form of tracheotomy tube in place show that the respirations become less frequent and demand a smaller degree of muscular effort than in the case of the ordinary tracheotomy tube. The positive expiratory tension is maintained and a more perfect oxygenation of the blood is ensured. Another advantage claimed for this device is that by compelling the patient to expire through the larynx, it brings about systematic gymnastics of the laryngeal structures and tends to prevent the development of laryngeal stenosis.

*"Le Traitement des Sténoses Aigues du Larynx." Par le Docteur Guillermo Zorraquin, Chef de Clinique de Chirurgie a l'Hopital de Niños de Buenos Aires. Paris: Vigot Frères, 1914.

FULL-TIME HEALTH OFFICERS.

A RETROSPECT of sanitary work in this country will show a very great advance during the past fifty years, yet a survey of present conditions will convince any one that we are still far from an attainment of the ideal. The community has not yet awakened to the importance of preventive medicine or realized that the surest way to avoid devastating epidemics is to be always in a state of sanitary efficiency. The American people seem to feel in regard to disease, as they do in respect of war, that sufficient to the day is the evil thereof, that they can cope with any emergency when the time comes, and that it is foolish to waste energy and money in getting ready to meet conditions that may never arise. Fortunately we have in the Public Health Service a body of trained sanitarians who are quick and competent to respond to any call, as they are doing now in New Orleans in fighting the plague; as they did in the same city in 1905 in repressing

a yellow fever invasion, and in San Francisco a few years ago in eradicating the plague. This is good, but it is not the ideal nor even approaching it. New Orleans in 1905 and 1914 and San Francisco in 1907 should have been in condition to protect themselves from any ordinary attack of epidemic disease without calling upon the national health authorities for anything but advice and general guidance.

In an address delivered some time ago, at a meeting of the Association of Life Insurance Presidents in this city, Surgeon General Blue of the Public Health Service called attention to the fact that the public health machinery of this nation consists of four distinct groups, upon the integrity and correlation of the forces of each of which depends the perfect working of the whole. The sanitary arm of our government having for its function the protection of all the States against all of the outside world and the protection of these same States one against the other constitute the first of these groups. It is its duty to study the great problems in disease warfare and to devise the grand tactics upon which the conduct of the lesser schemes and engagements may be based. It is its function to assist the State and local health authorities so that sustained effort may be gained and solid results obtained. Its strength lies in the fact that the members of its combatant forces have adopted hygiene and sanitation as their life work without the diversion of other interests.

The second, third, and fourth divisions of our public health machinery are the State, county, and municipal health organizations, respectively. Perhaps the most crying need of these three last-mentioned groups, Blue said, is for full-time health officers. The policy of part-time health officers is in the end far more expensive than the employment of officers whose single purpose is the sanitary service of their fellow men, for the worker in the field of public health does more for the moral as well as the sanitary uplift of the nation than any other official agency. Adequate remuneration should be paid in order to secure men who will devote themselves whole-heartedly to sanitary work. The great universities have provided courses for the training of public health officers, and at the present time the United States Public Health Service is training its officers by advanced studies and opportunities for independent research so that they can rise to the sanitary occasion. It is equally important that the State, county, and municipality should have trained men who can devote their entire energies to their work.

GUN DEAFNESS AND ITS PREVENTION.

A SUBJECT of timely interest and importance and one that is closely allied to the subject of the industrial diseases in general, is that of the injuries to the ear resulting from loud concussions. What may be regarded as one of the minor accidents of war is nevertheless, because of the large number of individuals concerned at the present time, one that cannot be ignored. Moreover, the aural injuries to which the soldier is exposed are no different from those of the boilermaker, of the structural iron worker, of the sportsman, and of those who are exposed to the shriek of the railway whistle when a train is passing through a tunnel or covered station. Jobson Horne in the *Lancet*, August 15, 1914, points out that the report of a piece of artillery, the concussion of an explosion, or the firing of a cannon close to the ear may exert its injurious effects upon the nerve terminals of the ear, may cause rupture of the drum membrane, and may even result in irremediable deafness. During the Russo-Japanese war, among the 1,791 men who were wounded in the naval engagements there were 116 cases of concussion of the labyrinth and rupture and congestion of the tympanic membrane, which cases represented 7 per cent. of the wounded who survived. The injuries to the drum and to the nerve endings are due to the sudden condensation or rarefaction of the air in the external auditory meatus. As a rule one ear is more affected than the other. Politzer states that with the improvements in modern artillery ruptures of the drum membrane are now scarcely ever met with. This is attributed to the introduction of breech loaders and also to the fact that the serving party withdraws to a distance of about twelve paces with the exception of one man who attends to the firing, but who also stands at a considerable distance.

In naval warfare, however, the gunners cannot be protected in this manner. Experience has taught the gunner that by keeping the mouth open so as to equalize the air pressure on each side of the drum membrane the unpleasant consequences of concussion may be diminished. The toothpick that is chewed by naval officers while serving the guns partly fulfills this requirement, although a piece of rubber rolled between the teeth would be still better as a means of keeping the mouth partly open. The Japanese naval surgeons distributed pledgets of absorbent cotton to the entire crew with the instruction that the ears be plugged up during the firing of guns. In spite of this measure, possibly on account of its careless application in individual cases, many instances of deafness resulted. In 1911 the British Admiralty advised the use of an aural plug consisting of a mixture of plasticine and cotton-wool. Jobson Horne believes that an efficient aural plug should be close-fitting and impervious, and while reducing the intensity of sound should not prevent hearing; it should be easy to insert and easy to remove intact; it should be nonirritating; it should be inexpensive so that the same plug may not be used repeatedly; and, above all, it must be as nearly antiseptic as possible. Cotton-wool when inserted sufficiently tightly is not easily removed intact and does not long remain sterile when handled by men engaged in gun-firing. The ear plugs made of vulcanite, rubber, or celluloid cannot be supplied to fit exactly the channel of the ear. They must be made of a substance that retains its shape without hardening or softening and remains ever plastic. A substance having the consistency of jeweler's wax may be produced and may be made to fulfill all the requirements of effectively plugging the ears and at the same time of preventing infection.

Suprarenal Virilism.

Nothing need surprise us to-day in the realm of affections due to aberrations of organs of internal secretion. Hardly two years ago we read of the extraordinary power of thyroid extract on a youth with arrested development in no wise cretinoid, the practical outcome having been that he attained the stature demanded for army service. A condition termed suprarenal virilism has been described by Ballez and Tuffier, who recently reported an extraordinary case (abstracted in the *Berliner klinische Wochenschrift*, July 27) in which an old woman was transformed by visceral disease into the simulacrum of a male. The woman was 62 and a sufferer from metrorrhagia (due to supposed fibroid) and diabetes. The latter affection was believed to contraindicate surgical intervention. It showed, however, marked improvement under diet. At this period the woman developed a strong beard and mustache, her face became florid, and the male type of baldness (frontoparietal) began to appear. The voice changed to the masculine type, the muscles began to develop strongly, the clitoris increased in size, measuring four cm. in length, and a prepuce of corresponding size developed. Years had elapsed since the menopause. The woman now preferred rough manual labor to feminine tasks. Eventually the enlarged uterus was extirpated and found to be the seat of simple hypertrophy only. The adrenals were found to be the seat of fibrolipomatous growths, which were not disturbed.

News of the Week.

Health of the Canal Zone.—The report of the Chief Health Officer of the Department of Health, Panama Canal, gives the total number of deaths from all causes among employees during the month of June as 20, of which 13 were due to disease, giving a death rate from disease of 3.28 per 1,000 per annum, as compared with 5.74 for the preceding month and 3.27 for the corresponding month of last year. The total number of admissions to hospitals and quarters was 1,511, or a rate of 381.09 per 1,000 per annum, as compared with 407.92 for the preceding month, and 472.50 for June, 1913. No cases of yellow fever, smallpox, or plague originated on or were brought to the Isthmus during the month. The diminishing death rate in the Canal Zone and the increasing death rate in the city of Panama, which has been noted for some time, is believed to be due largely to a shifting of the population from the Canal Zone to the city. The census which is now being taken will settle this point. The total population of the Canal Zone is now estimated at 54,655, among which there were 42 deaths due to disease, giving a rate of 9.22 per 1,000 per annum, as compared with 12.93 for the preceding month and 12.39 for the corresponding month of last year. In Panama City with an estimated population of 47,172, there were 150 deaths from disease, a rate of 38.16 per 1,000 per annum as compared with 32.56 for the preceding month and 30.02 for the same month of last year. In Colon, with an estimated population of 20,232, the deaths from disease numbered 44, the rate being 26.10, as compared with 30.25 for the preceding month, and 21.34 for June, 1913. The work of sanitation and the quarantine service have been carried on as usual through the month.

Public Health Service.—Boards of commissioned medical officers will be convened to meet at Washington, Boston, Stapleton, N. Y., Chicago, St. Louis, New Orleans, and San Francisco, on Monday, October 19, 1914, for the purpose of examining candidates for admission to the grade of assistant surgeon in the United States Public Health Service. Candidates must be between 23 and 32 years of age, graduates of a reputable medical college, and of good moral standing. The examinations are: 1, physical; 2, oral; 3, written; 4, clinical. Successful candidates will be numbered according to their attainments on examination, and commissioned in the same order. Assistant surgeons receive $2,000; passed assistant surgeons, $2,400; surgeons, $3,000; senior surgeons, $3,500, and assistant surgeon generals, $4,000 a year. For invitation to appear before the board of examiners, application should be made to the "Surgeon General, Public Health Service, Washington, D. C."

Peddlers' Licenses.—The New York City Department of Health and the Department of Licenses have determined to extend the scope of the medical examination now made of applicants for peddlers' licenses, and to include a Wassermann test in each instance. Hereafter, it is stated, a license will be denied to any tuberculous person whose sputum shows the presence of tubercle bacilli, and to any one whose blood gives a + + Wassermann reaction.

Infant and Child Mortality.—The New York City Department of Health has recently compiled some interesting figures in an investigation in the deaths and death rates of infants and children in the different age periods, the suggestion having been made that the efforts of all organizations to prevent infant mortality consisted simply in keeping babies alive during the first year only to have them die during the second or third years. The investigation extended over the last ten years, and a comparison was made between the first five-year period and the second. For infants under one year of age, the average annual death rate from 1904 to 1908 was 149.2 per 1,000; from 1909 to 1913 it was 114.6, a decrease of 23 per cent. For children between one and two years, the rate for the first period was 48.4 per 1,000, and for the second period 36.3, a decrease of 25 per cent. For children between two and five years, the rates were 15. and 10.9 for the respective periods, a decrease of 27 per cent.; while for all under five years the rate was 56.8 for the first period, and 42. for the second, a decrease in the entire infant and child mortality of 26 per cent. The total number of deaths of children and babies under five was 25,542 in 1904, rose to 25,794 in 1907, and then fell steadily to 20,711 in 1913. The deaths of infants under one year numbered 16,215 in 1904; 17,437 in 1907, the highest mark, and 13,780 in 1913. The figures show that the work which the Bureau of Child Hygiene and the allied agencies in New York City have been carrying on during the past five years has been highly successful, and that its influence has extended not only through the first year of life, but throughout early childhood.

Children's Haven Opened.—In the presence of a large number of guests on August 29, Health Commissioner Goldwater formally opened the new Children's Haven at Far Rockaway, New York. The home is intended for the care of children whose widowed mothers are in hospitals, and has accommodations for thirty-five.

An Unusual Suit.—Alleging that his health has

been permanently injured by the application of a carelessly prepared local anesthetic a resident of Plainfield, N. J., has brought suit against a New York firm of druggists to recover $50,000 damages. The complaint charges that instead of following the prescription of the plaintiff's physician the druggist substituted alcohol for a normal saline solution in the anesthetic.

Compulsory Vaccination.—The Commissioner of Education of New York State has recently notified the officers of the public, parochial, and private schools throughout the State that no pupil is to be admitted for attendance unless he or she has been vaccinated, as required by law, and this has led school officers to apply to the Attorney General for a construction of the vaccination law. In his opinion Attorney General Carmody says: "Children in parochial schools should be vaccinated, as are children in the schools supported at public expense. It is apparent that the danger of contagion is existent in parochial schools as well as in schools supported by public money. The purpose of the statute being so plain, good citizens will not question its application, but in recognition of a policy will accede thereto. The difficulty of penalizing a parochial school which existed when Attorney General Cunneen examined the question some years ago has not been removed from the present statute. However, the ordinance powers conferred upon municipalities and the general powers of local boards and of the State Commissioner of Health are such that I believe vaccination could be enforced where schools not supported by the public money endanger the health by persistently refusing to comply with this highly commendable requirement."

City Death Rate Low.—During the week ending August 22, in spite of the very severe heat which prevailed, the death rate in New York was 0.4 point lower than that of the preceding week, and only 0.04 point higher than the rate during the corresponding week of last year. For the first thirty-four weeks of 1914 the death rate was 14.16 per 1,000 of population, against 14.46 for the same part of 1913.

Fire Near Hospital.—A small fire in the engine room of the Roosevelt Hospital, New York, on August 26, caused some alarm because of the smoke which drifted through the corridors, but was extinguished before any damage had been done.

Condemn Boylan Law.—At a meeting of the executive committee of the Medico-Pharmaceutical League, held in Brooklyn on August 24, a discussion of the Boylan law resulted in the feeling that the law as it stands at present is too complicated to be practical, and that it is difficult of construction. It was suggested that a new bill should be drawn by a competent committee of physicians, pharmacists, and dentists, who would be better fitted to handle the problems involved than would non-medical men.

A Journal Devoted to Anesthesia.—Recognizing the need for a journalistic medium devoted especially to the practice of surgical anesthesia, the *American Journal of Surgery* announces that beginning with the October issue, and quarterly thereafter, it will publish a thirty-two page supplement dealing exclusively with anesthesia and analgesia. This supplement will be a complete journal within a journal, containing editorials, contributed articles, and communications, abstracts, transactions of societies, and book reviews. It has been adopted as the official organ of the American Association of Anesthetists and the Scottish Society of Anesthetists. The editor of the supplement will be Dr. F. Hoeffer McMechan of Cincinnati, who will be assisted by Dr. James T. Gwathmey, New York; Dr. Willis D. Gatch, Indianapolis; Dr. William Harper DeFord, Des Moines; Dr. Charles K. Teter, Cleveland; Dr. E. I. McKesson, Toledo; Dr. Isabella C. Herb, Chicago, and Prof. Yandel Henderson, Yale University.

Gifts to Charities.—By the will of the late Benno Neuberger of New York, bequests of $500 each are made to Mount Sinai Hospital, the Montefiore Home, the Lebanon Hospital Association, and the Beth Israel Hospital.

The Montefiore Home also receives a bequest of $2,500 under the will of Albert Rich, for the endowment of a bed in memory of the testator's parents.

By the will of the late Miss Hessy R. Miller of Philadelphia, the sum of $5,000 is bequeathed to the Methodist Hospital of that city, for maintenance.

The Philadelphia Home for Incurables has received a bequest of $15,000 from the estate of the late Mrs. Mary J. Van Syckel for the maintenance of two free beds.

The Jewish Hospital of Philadelphia by the will of the late Miss Sophia Glueck receives a gift of a house at 3010 Nevada street, Philadelphia.

Personals.—Dr. M. Zigler announces the removal of his office to the Physicians' Building, 40 East Forty-first Street, New York.

Dr. M. I. Blank of this city has removed to 35 West Eighty-first Street.

Obituary Notes.—Dr. CLARENCE K. ALGER of Swarthmore, Pa., a graduate of Temple University, Medical Department, Philadelphia, in 1909, and a member of the American Medical Association, the Medical Society of the State of Pennsylvania, and the Delaware County Medical Society, died at his home on August 16, aged 45 years.

Dr. ALEXANDER S. LEVERTY of New York, a graduate of the College of Physicians and Surgeons, New York, in 1890; clinical instructor in medicine, Department of Neurology, Cornell University Medical College; physician to the neurological clinic, Cornell Dispensary; clinical assistant in neuropathology at the Post-Graduate Hospital, and a member of the New York Neurological Society, died suddenly, from heart disease, at his home on August 28, aged 48 years.

Dr. WESTLEY ROGERS WALES of Cape May, N. J., a graduate of the Jefferson Medical College, Philadelphia, in 1891, at one time county physician for Atlantic County, a member of the Board of Freeholders of Cape May County, and a member of the Board of Health of Cape May, died at Atlantic City on August 11, aged 45 years.

Dr. WILLIAM G. RALSTON of Evansville, Ind., a graduate of the Medical College of Evansville in 1873, and a veteran of the Civil War, died at his home, on August 11, aged 95 years.

Dr. SAMUEL ALEXANDER NICHOLSON of Haverhill, Mass., a graduate of the College of Physicians and Surgeons, Boston, in 1904, died suddenly on August 17, aged 40 years.

Dr. WILLIAM HENRY CARR of Lancaster, Penn., a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1883, and a member of the American Medical Association, the Medical Society of the State of Pennsylvania, and the Lancaster County Medical Society, died at his home on August 2, aged 53 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

"WHOLESALE EXTRACTION" OF TEETH FOR ORAL SEPSIS —THE WAR NEWS—PRIZES, SCHOLARSHIPS, MEDALS AT THE COLLEGES—OBITUARY.

LONDON, August 21, 1914.

ORAL SEPSIS, its dangers and radical treatment by extraction of teeth has for a long time been a subject of discussion among practitioners of all branches of the profession, particularly in the dental specialty. It has long been recognized that the sacrifice of a tooth or two will suffice in many cases to cure a restricted pyorrhea which, if neglected, would be likely to spread and which had indeed resisted other treatment. This being so, the tendency is to refer these cases to the dentist who naturally resorts to the measure which has proved so effectual. It is here that the question arises as to the limit of the operation and one would imagine that should be determined by the extent of the disease in each case. With increased knowledge of the progressive nature of the lesion and improved appliances, fear of ill consequences following operations has diminished until what has been termed "wholesale" extraction has been practised by a number of dentists and has been sanctioned by others as legitimate surgery. This extreme is the extraction of the whole of the teeth for a case of extensive chronic pyorrhea as a cure of the condition and a safeguard against the oral sepsis involved becoming general septic poisoning, apart from which we are assured that many invalids recover their health soon after exchanging their natural for an artificial denture. Here we generally consider that American dentists are ahead of ours so I will not discuss the matter fully but report our recent proceedings.

At the end of July a protest against "wholesale" extraction appeared in the *Lancet* from the pen of Sir James Goodhart. This elicited replies from some of those dental surgeons who have advocated the method and will not admit his assertion that "a harmful practice has come into vogue that needs to be held up." On the other hand one meets those who acknowledge that extremes are dangerous and perhaps some have gone too far. It is pretty certain that many people have retained a number of serviceable teeth after having been recommended to part with them all. On the other hand it is frequently urged that formerly it was too common for decaying teeth to be left when they were obviously injurious as sources of oral sepsis.

Free discussion of such questions between practitioners can only do good. It is otherwise when the differences of opinion spread to the public—or rather to that section which deems itself competent to judge them by its own intuition. That this question has found its way to such critics was forcibly impressed on me a few days ago when a healthy woman of 27 with an almost complete set of sound teeth—the envy of her friends—asked me if I approved of the new dentistry, that is she explained getting rid of all the teeth as soon as one or two decay. Surprised, I exclaimed surely you do not think of parting with yours, to which the response was "No, but it has been suggested." By questioning closely I elicited that it was not a dentist but "only friends who knew all about the plan," which they assured her was a preventive of worse things. "If one became diseased others might follow." To which I responded that if one finger or toe became diseased the same might be said of its fellows, but was met by the retort that a toe was more important than a tooth, so I limited the comparison to a nail and told the lady that surgeons are sometimes obliged to evulse the great toe nail but they do not extend their operations to the other toes of the foot. I added something about the monstrous absurdity of non-professionals assuming to decide such questions.

The outbreak of war has of course deranged many medical as well as other plans. It will not be necessary to trouble you with many items of war news, the most important you will receive as soon as we do and will be able to form your own estimate of what may be the results. Reports and rumors abound and the separation of the true and false is difficult on their arrival as you very well know. I may assure you that the profession is doing its duty as earnestly as any part of the community. The Red Cross Society, Hospital, and Infirmary authorities, and numerous institutions are meeting the emergency with determination.

The two Royal Colleges of London have managed to hold special examinations for candidates who desire to go to the front. In some instances students who have not quite finished some part of the curriculum or have had to take up some special subject will be admitted to the special examination on a report from their examiners that they had nearly reached the standard.

The Colleges have awarded the Gilbert Blane naval medal to Surgeon G. F. Syms, R.N.

The R. C. P. London and University of Edinburgh have awarded the Murchison Scholarship in Clinical Medicine to C. J. Marshall, M. B. London, of Charing Cross Hospital.

Surgeon-General Sir Anthony Home, V. C., K. C. B., died on August 9, aged 87. He qualified M. R. C. S. England and M. D. St. Andrews in 1847 and the next year joined the army medical service in which for 38 years he worked, always with credit and in many responsible positions with distinction, retiring in 1886. In the Crimea he was in the battle of Balaklava and the siege of Sebastopol, earning the medal and two clasps; in India at Lucknow with more medals and the V. C. In China and New Zealand C. B. and medals. In Ashantee, medal and the C. B., became K. C. B. In 1894 he was awarded a pension for distinguished and meritorious service. Many interesting notes of his work are contained in his "Service Memories," published in 1912 (Arnold) edited by Lt.-Col. Melville, R. A. M. C.

The death is also announced of another army surgeon, Lt.-Col. W. Bullen Day, R. A. M. C., lately Deputy Asst. Director of Medical Service, London Division. He graduated M. B., Ch. B., Dublin, in 1884, and joined the army medical service the next year. He took part in the South African war, gaining the Queen's Medal with three clasps and the King's with two.

Dr. Walter Acton died rather suddenly on the 8th of August, aged 88. He qualified in 1850. He served for some time in the Crimea, having volunteered for the war after which he practised in the country for several years, retiring in 1887. He took great interest in public work, was a guardian of the poor and occupied other positions in Christian and philanthropic movements.

Dr. Carthew Davey of Liverpool died on the 11th inst. of typhoid. Previous to the attack he was in

the enjoyment of good health. He was a member of most of the medical societies of Liverpool, enjoyed a good practice and was highly esteemed.

OUR BERLIN LETTER.

(From Our Regular Correspondent.)

INTERNATIONAL CONGRESS OF UROLOGY—ANESTHESIA IN UROLOGY—PRESACRAL CONDUCTION ANESTHESIA—SURGICAL INTERVENTION IN DISEASE OF BOTH KIDNEYS—BENEFICIAL EFFECT OF REMOVAL OF ONE DISEASED KIDNEY UPON A DISEASE PROCESS IN THE OTHER—DECEPTIVE RESULTS OF NEGATIVE FUNCTIONAL TESTS OF RENAL ACTIVITY—CANCER OF THE PROSTATE—ITS RELATION TO PROSTATIC HYPERTROPHY—IMPORTANCE OF RADIATION THERAPY—PROUST'S MODIFICATION OF THE PERINEAL OPERATION—BACTERIURIA, ITS TYPES AND THE MODES OF COMBATING IT.

BERLIN, July 25, 1914.

AT the International Congress of Urology which met in this city early in June a number of interesting papers were presented. The first theme was that of anesthesia in urology. Bier of Berlin maintained that with few exceptions urological operations can be carried out under local anesthesia. In the case of particularly painful areas a few whiffs of ether may be employed. The best method of local anesthesia available for the lower portion of the urinary apparatus is Braun's method of presacral conduction anesthesia in which the sacral nerves are rendered anesthetic immediately beyond their exit from the sacral foramina. For the mucous membrane alypin is recommended. Spinal anesthesia in these cases, although not advocated as much as formerly, nevertheless promises much in the future, provided that a less toxic remedy than is now available can be found. For general anesthesia the open-ether method is the one of choice. Cabot of Boston places great stress on the prevention of shock in the anesthetization of the urinary organs. As a general anesthetic he prefers nitrous oxide-oxygen. Federow of St. Petersburg commonly uses intravenous hedonal anesthesia in operations on the kidneys.

On the second day the subject that came up for discussion was that of the removal of a kidney when both organs are diseased. Legueu of Paris dealt with this subject under three headings: (1) If both kidneys are affected with the same disease, as with tuberculosis, the more seriously affected organ may be removed, with the result that a beneficial influence on the remaining organ will thereby be exerted. (2) If the second kidney is affected with an inflammation of another type, the operation is not contraindicated. Usually the second kidney is the seat of an inflammatory process that subsides upon the removal of the first kidney. Great caution is here necessary, and particular weight should be given to the results of functional tests. (3) With reference to the determination of the functional capacity of the remaining kidney all known methods of testing should be employed. Casper of Berlin maintained that in the presence of doubtful results following the functional tests every operation is an extremely risky one. A reserve capacity of the kidney that comes into play when great demands are made on this organ has never, in his experience, been observed. Rovsing of Copenhagen attributes value only to positive results in the case of the functional tests, for if one is guided in all instances in which negative results are obtained, one may be constrained in some instances to withhold operation when such operation may be the means of saving life. Kümmel of Hamburg in 159 cases that he has operated on has used the method of cryoscopy with greatest advantage. Other speakers referred to the superiority of the determination of the Ambard coefficient.

Cancer of the prostate was the subject of a paper by Wilms of Heidelberg. He asserted that 20 per cent. of all hypertrophied prostates become malignant. The diagnosis of cancer is made presumptive by the presence of pain and dysuria, and the induration and nodular character of the gland. In this instance the gland should be removed by the perineal route, after which radium and the *x*-rays should be employed. Verhoogen of Brussels emphasizes the diversity of the course of cancer of the prostate and the consequent difficulty in its diagnosis. In some instances there occur an extraordinarily rapid growth of the tumor and an early death of the patient. In other cases there is a slow growth which may extend over a period of many years. For this reason one should make a diagnosis as early as possible. If the growth has broken through the capsule of the prostate the result of an operation is doubtful. Only individuals that are not too weak and in whom the renal function is good should be operated upon. Radium treatment is to be resorted to in every case, even though instead of cure it produces only improvement. In some instances radium changes an inoperable into an operable case. Proust of Paris reported a marked modification of the perineal operation. It is necessary to remove both the prostate and the seminal vesicles. For this purpose it is necessary to expose the posterior surface of the prostate and seminal vesicles and to turn these down in one flap. In this manner it is possible to free the ureter and by getting it out of the way to complete the operation more thoroughly. Freudenberg and Israel of Berlin doubt that one-fifth of all cases of hypertrophy of the prostate become malignant.

Bacteriuria was the last subject that came up for discussion. Sarter of Basle divided these cases into the autocthonous and the excretory bacteriurias. The former may be primary, but may also be associated with an inflammatory process. The same bacteria may evoke in one portion of the urinary tract a bacteriuria and in another portion an inflammation. The disease may affect the bladder and kidneys or may arise from a focus in the male genital apparatus. Although the prognosis is good the cure is often problematical. Biedle of Prague perceives the greatest difficulty in the question as to why the bacteria in the bladder do not affect its mucous membrane. He attributes this to an acquired immunity of the bladder from the prolonged abode of bacteria in its interior. The passage of bacteria from the intestine to the bladder may occur by way of the lymphatics as the result of the slightest injury of either organ. Tuffier of Paris employs vaccines with success in cases in which bacteriuria is the result of a blood infection, but not in cases of bacteriuria of exogenous origin. Freudenberg of Berlin demands a sharper demarcation between the different types of bacteriuria and calls attention to the fact that even clear urine may contain bacteria; the aim should be to produce not merely a clear but also a bacteria-free urine, all the more since in certain bacteriurias with an alkaline reaction of the urine there is the danger of producing phosphatic calculi.

1. The Spleen with Reference to Hemolysis and the Hemolytic Anemias.—H. C. Moffitt states that since recognition of the fact that only red-blooded animals have spleens, the interest in the relation of the organ to blood formation has naturally been great. In the human embryo there can be no question of the production of orythrocytes in the spleen, but there can be no question also that this production ceases at birth and that in later life the spleen is normally not concerned in the regeneration of red cells. There is reason to believe, however, that even normally the spleen exercises a certain degree of inhibition upon the bone-marrow, influencing the formation and addition to the circulation of both red and white cells. In disease this inhibition may be increased and may lead to anemia and leucopenia. It seems probable that the spleen is a depot for iron derived from destruction of blood and tissue cells and that the liver stores the iron coming to the body in the food. After splenectomy there is a marked reduction of erythrocytes and hemoglobin when the animals receive but little iron in the food, and there is a rapid improvement when iron is added (Bayer). Through its power of contractility, afforded by the content in smooth muscle and elastic fibers the spleen may vary its store of blood considerably and may, perhaps have some influence upon gastric and hepatic hyperemia. The thymus occasionally enlarges after splenectomy and perhaps may compensate for the loss of lymphocytic production in the spleen; enlargement of the thyroid has also been observed. The lymph and hemolymph glands are often involved in infections or general diseases like lymphogranulomatosis, pernicious anemia, and leucemia, which affect the spleen as well. Owing to the hyperemia and enlargement in the course of most infectious diseases the spleen has enjoyed a certain reputation as a power for good in the struggle with infection. There is no evidence, however, to show that immune bodies are more favorably developed in the spleen than in other organs. Remarkably interesting work has recently been done by Murphy in regard to the defensive mechanism of the spleen in the chick against the implantation of heteroplastic tissue. Rat sarcoma can be grown freely in chick embryos, but only until the spleen begins to develop. If a piece of adult spleen be planted in the embryo the same resistance to invasion by foreign tissue is established. Normally there is a remarkable balance between hemolysis and hematopoiesis. The bone-marrow reacts delicately to the increased carbon dioxide tension of the blood, to the products of erythrocytic disintegration, and to many chemical and infective agents, and is held in check possibly by an inhibitory influence of the spleen which may prevent the entrance into the blood stream of immature forms or an excessive number of erythrocytes. Chronic family jaundice (congenital hemolytic icterus) may be taken as a type of the hemolytic splenomegalies. The disease is most often hereditary or familial, but there are acquired forms as well. The icterus which characterizes congenital hemolytic icterus is slight or moderate and may be present from birth or may not appear until the tenth or fifteenth year or even later. There are rare cases in which it may even be absent—the complex being recognized in these cases by the large spleen, the increased corpuscular fragility, and the familial association. The acquired form of hemolytic icterus presents, as a rule, a decidedly graver clinical picture than the congenital. Anemia is often much more marked and predominates over icterus. Eppinger has dwelt upon the similarity of the pathological changes in the spleen and other organs in hemolytic icterus and pernicious anemia, and has emphasized the identity of many of the clinical symptoms. As regards Banti's disease, it is noted that tuberculosis and syphilis of the spleen may last for years and give rise to splenomegaly, to anemia, and to hemorrhages. Cases of splenomegaly with hemorrhages from the stomach and bowel should always suggest splenic vein thrombosis. There can be no question from the many reports now recorded that splenectomy may lead to a permanent cure in Banti's disease. Eppinger has reported a number of instances of splenomegaly with peculiar clinical symptoms and has proposed to characterize them by the uncompromising name of "megalosplenic cirrhosis." Hanot's cirrhosis has lately been added to the group of hemolytic splenomegalies. Eppinger believes the hepatic changes are due to the thrombosis and rupture of the bile capillaries following hyperemolysis and excessive bile formation; clinically the cases resemble both hemolytic icterus and hepatic cirrhosis. The pathogenesis of hemachromatosis is still under discussion. The recent work of Sprunt suggests the possibility of a local origin of the pigment through autolytic changes in the cells of the liver and other organs, the cell degeneration taking place first and pigment deposits and cirrhosis coming later. The preponderance of evidence, however, favors the hemolytic origin of the disease. In the aleucemic myeloid splenomegaly lately described by Hirschfeld the enlarged spleen with varying types of anemia may lead to confusion with Banti's disease on the one hand, and more rarely with pernicious anemia on the other. The diagnosis in some instances may be possible only by finding evidence of myeloid metaplasia from splenic puncture. The Leishman-Donovan infection is also known as the Egyptian splenomegaly. In dealing with the group of so-called hemolytic splenomegalies one is well aware of the incomplete character of the present clinical and experimental evidence. There are still many unknown quantities in hemolysis, and although one is fairly persuaded that the spleen plays an important rôle, one is still ignorant of just how it acts. The mutual relations between spleen, marrow, liver, and lymph glands are still imperfectly understood. Hypersplenism may be compared to hyperthyroidism, and in splenic, as in thyroid disease, the triumphs of surgery have come through dealing with effects rather than causes.

2. Ergotherapy in the Treatment of Mental Disorders.—Eva Charlotte Reid notes that ergotherapy, although the most rational and productive of any of the general agents employed in the treatment of mental disorders, is still neglected to a deplorable extent in present-day institutions. The average hospital for the insane gives its patients no chance to forget the past, and makes no attempt to substitute new interests for those left behind in the home, society, or place of business. Work may be a great detriment or a valuable therapeutic agent in the treatment of mental disorders, according to whether or not it is scientifically applied. In institutions where much of the hard labor is done by the patients, and a certain amount must be accomplished, the tendency is to make drudges out of the willing and efficient workers, and to allow to remain in complete idleness those who require to be instructed, supervised, and handled with tact. The benefit to be

derived from the scientific application of ergotherapy will result in a threefold advantage—to the patient, the institution, and the State. The busy patient is happier and more contented, and deteriorates less rapidly than the idle one. If all the patients were employed an institution would require fewer attendants, there would be less destruction of clothing and furniture, and the hospital, and consequently the State, would reap the benefit. In every hospital for the insane, public and private, there is a vast amount of energy going to waste that might be utilized to make the institution largely, if not completely, self-supporting. Every hospital for the treatment of mental cases should have one or more vocational instructors, whose duty it should be to consult with the physician in regard to the employment of individual cases, to distribute the work to the various wards, to instruct the nurses in the oversight of the patients, to conduct classes in the various occupations, and to attend to the purchase of materials and the sale of articles manufactured. It is necessary to have nurses in charge of each ward trained in the care of mental cases and able to do some vocational work. In order to accomplish the best results with ergotherapy, it is necessary to commence early. As soon as the patient becomes accustomed to the new environment, and the initial excitement has subsided, work should be insisted upon. A new occupation is the most beneficial in convalescent cases and depressions, where there is a tendency to introspection and retrospection. The mental effort of learning to do something new distracts the mind and stimulates the faculties. It is likewise important that patients be put to work on something obviously useful. There are a few general rules which might be laid down in the application of the different kinds of work to different classes of cases. The only cases to which ergotherapy may be applied indiscriminately are the chronic alcoholic and drug habitués. The work of the epileptics must necessarily be circumscribed and spasmodic. Nevertheless, they should be urged to employ themselves constantly at something. They should be encouraged, as a rule, to stick to one kind of work. The treatment of the manic-depressive psychosis by ergotherapy is a problem which demands long experience and careful study and observation of individual cases. By the time such cases are received at the hospital the excitement is usually well developed, and the apparent superabundant energy of the patient is being wasted prodigally in purposeless, if not harmful, activity. To attempt to limit this activity by physical restraint is worse than useless, but to direct it into useful channels is a task which calls for the greatest skill, patience, and tact. The more like play the work can be made the better, and it should be such as to call for no continued mental effort or exercise of patience on the part of the patient. It is often necessary to try first one kind of employment and then another. If the patient can be made to work only a few minutes on the first trial, the length of time can be gradually increased. During an oncoming depression of manic-depressive insanity, work is, as a rule, harmful, and these patients should be relieved from the discharge of all duties, and, if possible, be made to remain in bed. In view of the fact that more than one-half of the permanent population of hospitals for the insane is composed of cases of dementia precox, it would seem that this class of cases offers the best field for operation in ergotherapy. To re-educate the vast army of demented patients in the hospitals for the insane would be a task which would involve an expenditure of time, energy, and money, which, in all probability, would not be warranted by the results obtained. The new cases of dementia precox can, however, with comparatively little trouble, be directed into better paths, to the end that the chronic wards in hospitals for the insane will be filled with patients who, although demented, will be quiet, tidy, industrious, and contented.

3. **The Use of a Section of the Scapula in Correcting a Nasal Deformity.**—O. A. Lothrop states that the various types of nasal deformity require entirely different operative procedures for their correction. The simplest type is that of the fracture-dislocation of the nasal bones, and the operation required in such cases consists in a re-fracture and then a reduction of the dislocation. A second type is exemplified in the lateral deviation of the cartilagineus portion of the nose. Another type may be noted in the aquiline deformity which requires a special technique for reduction. The irregular humps often found at the distal extremity of the nasal bones are amenable to special surgical procedures. Depressions of the nose bridge and destruction of the septal, supporting cartilage, so that the tip of the nose is depressed and unsupported, require the addition of material to fill in the depressions or support the tip. Trauma, syphilis, and abscess of the septum are the common causes for these destructive deformities. The author decided to experiment with a strip of bone from the free vertebral border of the scapula. Here one may obtain a thin, rounded strip of vascular bone, straight for two surfaces and its free border. This needs no shaping other than to determine the length and width required. Other advantages which may be mentioned are the safety of operating in this region, the superficial and easy access to the scapular border, and the facility with which a strip of bone may be removed—all tending to consume very little time. The author's patient was a man twenty-one years of age, who had been struck on the nose by a baseball bat. The nasal bones were dislocated to his left and there was a prominence at their distal extremity. There was no support from the cartilaginous septum, so that the tip of his nose had fallen and deviated to his right. What was left of his cartilaginous septum was fractured, deviated, telescoped, and cicatrized into a mass obstructing his breathing. The operation was performed under ether anesthesia with the patient in the recumbent position on the operating table. First, the septum was resected submucously in the usual way in order to remove all obstruction to breathing, and also to free the soft tissues of the tip which could then be raised and moved easily in all directions. A 3½-inch skin incision was made over the vertebral border of the left scapula. A strip of bone two inches long and about one-quarter of an inch wide was removed from the free border with bone cutting and wrapped in wet, sterile gauze. The patient was returned to the dorsal position, the nose re-sterilized, and a quarter-inch incision made in the under surface of the tip of the nose, half-way between the tip and the beginning of the columella. A subdermal passageway was made in the nose bridge extending to the distal extremity of the nasal bones. At this point the periosteum of the nasal bones was cut and elevated along the crest of the nose bridge up to the frontal bone. The nasal bones were now ground down with a rasp in order to remove the prominence and deviation to the left above referred to. The coarser bone filings were scooped out of the passageway with a curette and a graft which had been taken from the scapula was inserted through this passageway and under the periosteum until the end reached to the frontal bone. The incision in the tip of the nose was closed with two interrupted horsehair sutures and covered with a cocoon. Slight pressure was applied over the graft at its frontal end in order to hold it pressed against the nasal bones and to stretch the contracted soft tissues

of the tip. The patient made a good recovery. For four weeks a narrow strip of crèpe lisse was stretched from the tip of the nose to the forehead, being made adherent to the skin at these points with collodion and exerting just enough tension to raise the tip. Counter pressure was made over the frontal end of the graft by placing a ball of cotton between this point and the strip of crèpe lisse. In two weeks granulations had attached themselves to the periosteum of the graft, thus binding it to the nasal bones so that the graft was becoming firmly fixed. In three weeks the graft was quite solid, and in four weeks it was very rigidly held in place on the nasal bones and the dressing was omitted. By this time the skin of the nose had resumed its normal color.

1. Practical Application of the Luetin Test.—H. Noguchi states that during the past two years a large number of observations have been made in connection with the luetin test by different investigators. The following statistics are based upon the observations made by about fifty investigators: In primary syphilis the reaction is present in less than 30 per cent. of cases and the intensity of the reaction is usually very mild. In secondary syphilis the reaction was reported positive in 47 per cent. of 630 cases. The reaction is usually mild. In tertiary syphilis the reaction was found in about 80 per cent. of cases. The reaction is very severe in this stage of the disease (usually pustular form). Herzberg and Donitz reported 100 per cent. positive in 170 cases which were under observation at the University Clinic of Professor Bier, in Berlin. In congenital syphilis the reaction was reported to occur in about 70 per cent. of cases. Brown, who made the largest series of tests, found it present in 93 per cent. of seventy-five cases studied. The reaction becomes more distinct after energetic treatment. In syphilis of the nervous system the reaction is less frequently present in acute syphilitic meningitis than in the parenchymatous affections, such as general paralysis and tabes, where it has been reported positive in about 60 per cent. of cases. In visceral syphilis the reports of Wolfsohn, Stoll, and others show that the reaction is present in nearly 90 per cent. of cases; it is especially marked in the cases of aortic insufficiency. From the statistics of the luetin reaction one can easily see that the Wassermann reaction is much more constant among the primary and secondary cases, as well as in general paralysis, but the reverse is the case in chronic cases, especially in those under treatment. The significance of the luetin reaction in regard to the prognosis of syphilis appears to be a matter of great importance to the physician. The author himself often speculated as to why some paretic cases give a positive and others a negative reaction. It should not be at all improbable that paretics with a positive luetin reaction are still capable of deriving some benefit from an antisyphilitic treatment since the reaction is in a measure indicative of a mesenchymatous tertiary process. The future will determine this point.

2. The Complement Fixation Test in Gonorrheal Infections.—A. McNeil quotes the following conclusions which were published by Schwartz and the author in 1912 and which have subsequently been confirmed by other authors: A positive reaction denotes the presence or recent activity in the body of a focus of living gonococci. A negative reaction does not exclude gonococcus infection, but should be accorded considerable importance. A strong positive reaction is not to be expected earlier than about the fourth week, and then only in very acute cases with some complication. A positive reaction is not obtained if the disease is limited to an anterior urethra. A positive reaction does not entirely disappear until seven or eight weeks after cure. In other words if a strong positive reaction is obtained seven or eight weeks after apparent clinical cure the patient should be looked upon as still harboring gonococci. The technique of a complement fixation test is simpler than that of isolation of the gonococcus in culture, and the possibilities of error are less.

4. Clinical Types of Adiposis and Lipomatosis.—G. E. Price states that simple obesity or adiposity may exist without any associated symptoms. It is well known, however, that it is not unusual to find some slight tenderness in the fat of persons who are only moderately fleshy. In addition to this there may be present as occasional symptoms a moderate degree of asthenia, minor mental disturbances, and a tendency toward arthritic involvement. Simple obesity is frequently hereditary, although not all members of the family may be similarly affected. Nodular circumscribed lipomatosis is characterized by clearly defined single or multiple fatty tumors, which may be symmetrical in site or irregularly distributed. They are most frequently located about the neck, in the axillæ, over the trunk, or on the extremities. That this type may be accompanied by a variable list of constitutional symptoms, especially arthritic disorders, was probably first recorded by Koettnitz, who separated his lipomata into two groups, depending upon the presence or absence of general symptoms. In diffuse symmetrical lipomatosis the fatty masses have no capsule, but fade into the surrounding adipose tissue, and are also symmetrical in distribution, although not always simultaneous in appearance. This form is somewhat elective as to location, the tumors usually appearing in pairs in corresponding positions upon either side of the neck, although other parts of the body are by no means exempt. It appears as a rule during adult life and almost invariably in the male sex. The individual affected may be, and in fact usually is, of average weight. A history of alcoholism is common. Froelich's syndrone or dystrophia adiposogenitalis is, as the name indicates, of cerebral origin and the result of disease of the hypophysis. Adiposis dolorosa, or Dercum's disease, was described by Dercum in 1888, and has as its chief characteristic an accumulation of fatty masses variously situated, which are either spontaneously painful, painful upon manipulation, or both. Two other symptoms, but little less important and included among the four cardinal symptoms, are asthenia and psychic disturbances. Pathological changes have been found in the thyroid and pituitary glands, the peripheral nerve fibers and, less frequently, the nerve trunks. Sclerotic ovaries and undeveloped testicles have been reported. The author reports a case of this condition in a woman, aged thirty-two years, who complained of shortness of breath, marked general weakness, and depression without adequate cause. Her appetite was fair, her sleep irregular, and there was no complaint of headache. Her flesh bruised readily. Menstruation had been very irregular; at times it would be absent for several months, then she would have both menorrhagia and metrorrhagia. There was also attacks of abdominal pain and vomiting accompanied by an irregular temperature.

The patient was found to present general obesity with additional masses variously distributed over the abdomen, hips, and about the knees (generalized, diffuse). These masses had the "bunch of worms" feel and were exquisitely painful on pressure. During the time this case had been under observation the following interesting phenomena occurred: First would be periods of excessive weight, slow pulse, and normal or subnormal temperature, which condition would be greatly benefited by thyroid medication. Following this would be a period of comparative comfort of several months, during which all medication would be discontinued. Next would come a period of irregular temperature ranging from normal to 101 deg. F., with rapid pulse, vomiting, diarrhea, marked flushing, and extreme perspiration. She would also present a fine intention tremor of the hands and an excited, anxious mental state, and her weight would diminish rapidly, on one occasion reaching 182 pounds and on another 187 pounds. There was never any evidence of exophthalmos during these attacks. This condition would clear up slowly under rest in bed, sedatives, and digitalis; next would come a comfortable intermission of a few months, then with an increase in weight the cycle would commence all over again. The patient has passed through several of these circular phases while the author has been attending her. The second interesting feature presented by this case is the development of muscular cramps, which would appear during or just after the symptoms of hyperthyroidism. These cramps appeared in the extremities, chiefly in the feet and hands, which would at times flex so they could not be straightened voluntarily. The cramps during one attack recurred intermittently for about a month, then gradually disappeared. The patient had one or two similar attacks of variable duration. The history of this case points to a functional disturbance of the parathyroid glands.

5. **Experiences During the Late Balkan War.**—B. Jablons states that the surgical cases in Belgrade included for the most part minor surgical wounds, fractures, etc., which had not required immediate operation, or minor injuries which as a result of later infection demanded complicated surgical procedures. Of these the greatest number consisted of abdominal abscesses secondary to gunshot wounds of the abdomen, and brain abscesses secondary to perforating wounds of the skull. In addition there were quite a number of soldiers who, as a result of the long winter siege of Adrianople, had suffered very severe frostbite of the extremities. Many of these cases required amputations, and such cases were almost invariably sent back to the larger and more populous centers. The medical cases up to the fall of Adrianople, consisted for the most part of inanition and exhaustion fever, not a little typhoid fever, and intestinal affections such as dysentery of the Shiga and Flexner type. Weil's disease was also occasionally met with. The amebic form of dysentery may have prevailed over toward the Tschataldja line; in Servia, however, it was comparatively rare. The author was detailed as bacteriologist to work in conjunction with a unit of the German Red Cross Society, which had been sent to take charge of the medical department of a military hospital. Here first aid was given and emergency operations were performed. These consisted chiefly of amputations, the tying of arteries, and the preliminary setting of fractured bones. These cases were then immediately transported to the nearest or farthest military hospital, depending on the severity of the injury. As soon as these hospitals were filled the wounded were sent to the nearest civil hospital. Cholera worked greater havoc with the Bulgarians than with the Servians, not because of any greater precautionary measures on the part of the former, but because of the lesser number of men fighting on the side of the latter. The surgery at this time was limited chiefly to occasional trephinings, laparotomy for abdominal abscesses, and amputations for frostbites, of which there were a goodly number. Considering that the men had to do sentry duty in trenches filled with snow and ice, which in some instances reached up to their shoulders, and had to keep their weapons serviceable, it seems remarkable that a greater number were not affected. The frostbite was not limited to the feet and toes only, but in many instances the entire leg and even lower portions of the thighs were affected and had to be amputated. The horrors of war were never more clearly shown than in the case of these poor fellows who lost their legs or arms through the inclemency of nature and not through the shot and shell of the enemy. A few weeks later the character of the diseases seemed to change. Instead of the ordinary fevers due to inanition and extreme fatigue, diseases common to great bodies of men living under unhygienic surroundings made their appearance, viz., typhoid fever and dysentery. Most fearful of all was the occurrence of typhus fever.

4. **Bromoderma.**—L. Weiss, after describing a case of this condition, concludes that drug eruptions may simulate almost any known skin affection. A skin eruption starting suddenly without any prodromal symptoms is almost sure to be a medicinal eruption. The violence of development and the preponderance of the local over the systemic disturbances are characteristic of drug eruptions. The brevity of the acute stage and the quickness of defervescence constitute a notable asset in diagnosis. The usual four stages of the acute contagious exanthems, namely, the prodromal, the eruptive, the fully developed, and the retrogressive and desquamative stages, are wanting. The temperature never rises to the point shown by the acute exanthems and the affection of the mucous membrane is never so severe.

5. **Favus and Ringworm of the Nails.**—M. H. Foster states that while favus and ringworm of the nails are supposed to be rather rare, the finding of 101 cases among immigrants at Ellis Island during the first eight months of the present fiscal year indicates that these disorders are probably more common, at least among our foreign population, than has been supposed. Clinically the two disorders are alike. The nails are thick and brittle and sometimes even caseous. They do not seem to be painful or tend to cause an inflammation of surrounding parts. The process is chronic, and if untreated lasts indefinitely. The youngest patient observed was three years old and the oldest seventy-two.

Good histories were hard to get, but one patient said he had had the trouble fifty-two years. While the condition of the nails is highly characteristic, it may be simulated by syphilis, psoriasis, eczema, hypertrophy and atrophy, grave constitutional disorders, etc., but in these cases all of the nails are likely to be affected, while in ringworm and favus one or more are apt to escape. The organism generally appears as plain hyaline branching threads, showing here and there spores, usually not very distinctly. The palms of the hands and the fingers may be affected. The diagnosis between favus and ringworm is not usually easy, but if either disease prevails elsewhere on the patient it is probably the cause. In the series of 101 cases, eighty-four were ringworm and seventeen favus. About one in 5,000 of the immigrants was affected. The author does not have a very good opinion of medical treatment of these cases. The avlusion of the nail and the application of some germicide to the matrix may be justifiable. On account of the contagiousness and loathsomeness of these two diseases and the special danger when they affect the hands and nails they should be put among the class of notifiable diseases, and cases occurring in this country should be so placed as to prevent their spread.

9. **Public Health Work as a Career.**—J. A. Ferrell states that there are already more positions open for trained health officers than can be satisfactory filled. The demand is increasing all the time. It comes from federal, State, and city health departments; from the International Health Commission, and similar quasi-public health agencies; from the schools, and more recently from rural counties. The medical inspection of schools has made rapid strides in the last year or two in both city and country. Twenty-one States now have medical inspection laws, ten of which are mandatory, while in many of those States without special laws on the subject individual cities have inaugurated medical inspection systems. The medical inspection work is more and more being centered about the whole-time health officer. Maryland is looking for men to fill positions created by the sanitary district bill passed at the last legislature. New York State is in the market for a large number of trained health officers. North Carolina employs eleven whole-time county health officers at salaries that attract capable men irrespective of residence. Sooner or later all the States will exert that control over hygienic and sanitary conditions which a few now exert, and this will mean an ever increasing demand for public health officers to give their entire time to the community. Already some educational institutions are coming forward with special courses to train men for the new work. The "School for Health Officers" of Harvard is sufficiently well known, and at least five American universities—Harvard, Pennsylvania, Michigan, Wisconsin, and Tulane—now grant the degree of doctor of public health for special public health work over and above the requirements for the regular medical degree.

Deutsche medizinische Wochenschrift.

July 30, 1914.

Fatal Hematoporphyrinuria from Sulphonal.—Pförtner states that over 47 cases of this urinary find are upon record, the majority of which occurred soon after its introduction into therapy in 1889, before the safe dosage limits had been determined. There are also on record seven cases of the same condition due to trional and two from veronal. Fatalities from the use of sulphonal have occurred in which no hematoporphyrinuria developed. Colossal doses of the drug have also been taken which were followed neither by this accident nor a lethal result. A predisposition must, therefore,. be present. Women are more susceptible than men. The author's case occurred in a woman of thirty who appeared to be suffering from the maniacal phase of manic-depressive insanity. She had refused all medication *per os* and only became quiet for a short time after 1 mg. duboisine given hypodermically. Sulphonal was then mixed with the food, although the latter was administered with great difficulty. She ingested some four grams daily for two days and as she quieted down half that daily dose was given for several days more. These were the amounts mixed with the food, but the author concludes that at most not over ten grams of the drug found their way into the body. The woman now became very constipated. For the first three days following the last dose of sulphonal no urine was voided. On the fourth day urine of the characteristic postanic color came away. After this she became so restless that duboisine (0.5 mg.) was given. On the fifth day she collapsed, complained much of abdominal pressure, and died a few hours later. Urine passed involuntarily shortly before death stained the sheets—urine color. At autopsy the kidneys were found normal. The real causes of death were doubtless the constant agitation of nearly two weeks' duration and the defective alimentation and fatty state of the myocardium. Hematoporphyrinuria does not follow acute sulphonal poisoning, from a large single dose, but appears when the drug has been taken for a considerable period.

Mumps and Pancreatitis (?)—Dracinski and Mehlmann report three suspected cases of this association. Owing to the very mild character of mumps, autopsy finds are rare. In an extensive epidemic of this affection the author noted a peculiar syndrome in several cases. This comprised herpes, violent frontal headache, absence of stools, vomiting (suggesting ileus), collapse, fever with delirium, pain and tenderness above the navel, absent patellar reflexes, marked acetonuria, Cheyne-Stokes breathing and slowing of pulse. With the exclusion of meningitis which was not difficult, the diagnosis was pancreatitis. Vomiting and collapse pointed to an inflammation involving the solar plexus, while the absence of patellar reflex is accounted for by participation of the first lumbar nerve roots. Aceton intoxication may or may not have been responsible for the slow pulse and Cheyne-Stokes breathing. The author was then led to test a large number of uncomplicated mumps cases for the patellar reflex and found this absent in 10 per cent. He is entirely silent as to certain data, such as the stool finds, Cammidgo's reaction, etc., etc. Nor does he even allude to the vast significance of such cases for the subsequent development of child diabetes.

Acute Retention of Urine, a Rare Consequence of Morphine.—Czapek and Wassermann in nowise refer to acute suppression of urine, but to an acute retention due to spasm of the sphincter vesicæ. In all he records five cases, in four of which the drug was given by suppositories. The dosage was within safe limits and there were no symptoms of morphinism, save such inevitable phenomena as constipation. The action of the drug on the intestine seems to have extended to the bladder. We know at present that morphine causes spastic contraction of the pylorus and from analogy the sphincter vesicæ could be similarly affected. This discovery may throw some doubt on the nature of the oliguria and anuria which are so commonly seen in morphine habitués and which may be complicated with retention. At least under the latter circumstances the catheter should always be used. Again urinary retention so commonly seen after certain operations may be due in part or at times to the injection of morphine given before operation.

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

THE CHOICE OF PLAN FOR SUBSTANDARD RISKS.

THE plan selected in allowing for the extra mortality which is expected among underaverage lives should vary with the character of the risk assumed, the character of the risk being determined by the period during which danger may be expected. Hazardous risks may be divided into the three following classes:

1. The early or decreasing extra hazard. This hazard exists most commonly among applicants with family histories strongly tainted with tuberculosis. It is found also in certain conditions, such as the albuminuria of adolescence, in which it may be reasonably assumed that the applicant has a good chance of ultimately enjoying freedom from the disturbance. The extra mortality expected in the early years is most completely and efficiently covered by the lien system. As an illustration, we may take the case of an applicant with a history of tubercular trouble in the family combined with a physique that leaves some doubt of his ability to overcome the taint. The mortality is expected to be unfavorable in the early years of policies in this class, and to gradually approach the normal with those who survive the uncertain part of their lives. To offset this increased hazard, a lien or contingent debt of perhaps 50 per cent. is placed upon the policy, remaining level for perhaps five years and then running off in equal instalments during perhaps the next ten years. If the policyholder dies during the first fifteen years from any other cause than accident, the amount of lien standing against the policy at the date of death of the insured is deducted from the face value of the policy in paying this claim. In this way, the poor lives actually pay the extra premium themselves, and this is substandard insurance in the true sense of the word.

The lien system was formerly employed in the United States as well as in Great Britain and Canada, but was prohibited to companies doing business in the State of New York by the statute in the Armstrong Law which compels the companies to issue certain prescribed standard forms of policies. A company could, possibly, obtain permission from the insurance department of the state to take up the lien system again, but there has been little disposition so far to depart from the letter of the law. No company wishes to give an opportunity to a competitor to insinuate that it, the former, does not issue standard contracts, the public not being sufficiently conversant with the subject to understand the situation. Furthermore, the lien system did not always prove popular in the United States, some policy holders not relishing the idea that their contracts were good for only a certain part of their face value, even though the amount to be paid in case of death gradually approached the full value later on. For these two reasons, especially, no company has thought it feasible to invoke permission from the state authorities for renewing the lien system. A decidedly bad family history could be taken care of only by the lien system, but the companies prefer to decline a risk that cannot be covered by the rating-up system. One large company attempts to arrive at the same end as that accomplished by the lien system, by charging a higher premium which remains level for a certain number of years and then gradually becomes lower until the ordinary rate is reached. This plan is effective only when the impairment is quite mild, as a premium high enough to cover more serious hazards would be prohibitive. Nearly all companies transacting substandard business, then, adhere to the rating-up system for covering the extra risk in early hazards, but the plan is not rational, since the extra premium must be paid during the life of the policy and after the critical period has passed. Yet an injustice is done towards other policy holders if the premium charged is not high enough to cover the early hazard.

2. The constant extra hazard is one which remains stationary. This hazard most commonly exists among those following certain occupations and, according to the view held by some companies, among women. The rated-up policy covers this extra risk admirably. In order to ascertain the proper ratings, the mortality rate in each class must be estimated and the results then compiled into tables showing the number of years to be added to the age of the applicant, the premium charged being that due for the advanced age. A little reflection will show that the method of rating up lives a certain number of years is only satisfactory when there is a constant or increasing extra mortality.

3. Late or increasing extra hazard. This class includes such risks as overweights, rheumatism and gouty subjects, supposedly cured syphilitics, Keeley graduates, etc. The extra hazard in cases of this kind may be covered by the rating-up system and by the endowment form of policy.

The rated-up premium is a successful method for covering the extra mortality in a deferred risk if it is computed to the fine point of adjustment where it will protect the company without taxing the policy holder more than the impairment calls for.

The endowment policy fits the case with certain hazards which are not liable to arise until after a certain number of years. At the end of the stated time, the amount represented by the higher premium is refunded through the options and privileges stated in the contract. In other words, the transaction terminates, the company having protected itself, and the insured going his way with the critical period of his life still to face. It would be a useless procedure to attempt to provide for contingencies during the early years by an endowment policy. Unfortunately, the standard form of endowment policy exacted in accordance with the Armstrong Law allows the privilege of automatic extended insurance in case of lapse, so that a holder of an endowment policy has it in his power to exercise self-selection by stopping the payment of further premiums in the event of his contracting some chronic illness with the full knowledge that the face value of the policy will be paid in the event of his death during the extended period. Nevertheless, the form of policy is useful to companies which do not issue substandard policies, when it is advisable to issue a contract which will terminate at a certain age, after which the evil effects of some condition or circumstance are liable to appear.

All methods for dealing with substandard insurance are made up from the individual experience of each company, so that there are no universal rules, and guesswork is necessarily a large element in the process. Many risks are so far below the standard that they are not insurable on any plan unless prohibitive rates are charged, although a larger proportion of these applicants could be accepted with a lien.

Book Reviews.

THE SURGERY OF THE STOMACH. A Handbook of Diagnosis and Treatment. By HERBERT J. PATERSON, M.A., M.C., M.B. (Cantab.), F.R.C.S. London. New and Revised Edition, with Plates. Price, $4.00 net. New York: William Wood & Co., 1914.

THIS is a book that it is a distinct pleasure to read and to review; a work based upon the author's personal experience, which, as is well known, has been very extensive, and not a hodge-podge of compilation containing a mere sprinkling of original matter. Clear and concise descriptions of the pathology and symptoms of gastric and duodenal lesions, methods of examination, differential diagnosis, and the technique of operation, bring the essential points to the reader's attention with great force. One does not have to separate the wheat from the chaff—this has all been done by the author. Another point that deserves comment is that there is not a useless illustration in the book. The author has not succumbed to the popular craze for quantity, so there are no illustrations of bandage scissors or other instruments in every-day use and for this he deserves thanks as well as congratulations; but those which he has incorporated in the work are of high quality, the thirty stereoscopic plates illustrating the various steps of anterior and posterior gastroenterostomy being especially noteworthy.

The *x*-ray in the diagnosis of gastric and duodenal conditions has not been given sufficient prominence, at least from the American point of view; but this is not to be wondered at since American röntgenologists have completely outstripped the rest of the world in the development of radiologic diagnosis of gastrointestinal conditions. This is one of the very few points compelling adverse criticism. We cannot agree with Paterson's statement that "it is very doubtful whether any operation for gastroptosis is of real value." In our opinion the complete Coffee operation is a very valuable procedure; but the *complete* operation must be done, and not the simple suturing of the great omentum to the abdominal wall referred to as the Coffee operation by Paterson. His ideas upon early feeding by mouth after stomach operations are rather revolutionary, but this chapter and the succeeding ones on complications after gastric operations and the effects of gastrojejunostomy are exceedingly interesting. One of the most valuable parts of the book, however, is that dealing with ulcer of the stomach and upper part of the intestinal tract; for ulcer with its complications, early and remote sequelæ, forms the starting-point for most of the surgery of these structures, especially if one believes with Mayo that more than 70 per cent. of the cases of gastric cancer start from ulcer. This subject is rather exhaustively treated, while for the benefit of those interested in further study, lists of references are appended here as well as in many other parts of the book. We feel that we cannot recommend this work too highly.

TECHNIK DER SPECIELLEN KLINISCHEN UNTERSUCHUNGSMETHODEN. Unter Mitwirkung von Dr. K. BRAHM, Dr. W. FREY, Dr. JANUS, Dr. MEYER-BETZ, Dr. Fr. MÜLLER, Dr. G. NICOLAI, Dr. J. PLESCH, Dr. H. SCHADE, Dr. J. SCHMID, Dr. Th. STUMPF, Dr. W. WEICHARDT, Dr. G. WIEDEMANN. Herausgegeben von Prof. Dr. THEODOR BRUGSCH und Prof. Dr. ALFRED SCHITTENHELM. I Teil. Mit 359 Textabbildungen. II Teil. Mit 115 Textabbildungen, 1 farbigen Tafel und 1 Tabelle. Price, Parts One and Two, 36 Marks. Berlin und Wien: Urban und Schwarzenberg; New York: Rebman Company, 1914.

AT the present day it would appear difficult to devise a medical work of general applicability which should be new in type. The authors of this volume have, however, accomplished this seeming impossibility and have issued a book which is distinctly different in scope from any already existing. There is no lack of text-books which are devoted to the ordinary methods of clinical investigation, and in some of the treatises dealing with special subjects one may find described the more complicated procedures which are necessary in studying the problems of disease from the purely scientific or theoretical standpoint, but till now there has been no single work combining both aspects of the subject. The methods of attack of the two types of workers are steadily converging, however, for clinicians are becoming more scientific while at the same time the research workers are learning to vitalise their studies by taking greater account of the needs and problems of the practitioner. It has been the purpose of the authors to bridge this gap, and the book is intended to point the way for the actual application of the more refined and difficult laboratory methods to actual clinical medicine. Examination of the table of contents shows that practically every method of investigating the phenomena of disease apart from the ordinary physical signs is described in full detail. The latter have already been discussed in the "Lehrbuch Klinischer Untersuchungsmethoden" by the same authors of which the present work forms practically a second volume. It is impossible even to mention all of the subjects dealt with, but attention may well be called to the extensive sections on *x*-ray work, the use of the kymograph and the electrocardiograph, bacteriological technique, the methods of histological examination, and optical methods including the use of the colorimeter and the ultramicroscope. The entire first half of the second part is given over to the chemical study of metabolism, and there are extensive sections on the various physicochemical methods, together with a great deal of material on the ferments, including Abderhalden's studies. The work is a perfect storehouse of information and is remarkably complete, though occasional curious gaps are noticeable, for example the very unsatisfactory treatment of the methods for testing kidney function. A serious defect, especially in a book of this kind is the hopelessly inadequate index, but that is a fault from which few German books are exempt. The work is one which will perforce have a place in all laboratories, and it is to be hoped will also find its way to the shelves of progressive clinicians.

DEFENSIVE FERMENTS OF THE ANIMAL ORGANISM against Substances Out of Harmony with the Body, the Blood-plasma and the Cells; their Demonstration, and their Diagnostic Significance for Testing the Functions of Different Organs. By EMIL ABDERHALDEN, Director of the Physiological Institute of the University at Halle a/S. Third Edition. English Translation by J. O. GAVRONSKY, L.R.C.P., M.R.C.S., M.D., Halle a/S. and W. F. LANCHESTER, M.A. Price, $2.75 net. New York: William Wood & Company, 1914.

THIS is a translation of Abderhalden's well-known "Abwehrfermente" made from the third edition of that work. It is unnecessary to discuss the importance of the German author's theories or the position which they hold at the present time. They have attracted a large amount of attention and the widespread interest in the subject is sufficient justification for the publication of the translation. As a translation it is not wholly satisfactory; but that is almost inevitable in such a work. The book could be improved by the addition of an index.

INTERNATIONAL CLINICS. A Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles on Treatment, Medicine, Surgery, etc. Edited by HENRY W. CATTELL, A.M., M.D. Volume II. Twenty-fourth Series, 1914. Price $2.00. Philadelphia and London: J. B. Lippincott Company.

THIS number includes twenty-three articles on Diagnosis and Treatment, Medicine, Surgery, Obstetrics and Child Welfare. The article on insomnia by James J. Walsh is especially to be recommended as a sane and wholesome consideration of the subject. Articles on tuberculous joints by E. G. Beck and C. M. Jacobs are very interesting while Martha Vinton's paper on the Teaching of Sex Hygiene is the most attractive we have seen on that subject in a very long while. It is perhaps adapted to ideal conditions but is on a much higher plane than most of the material put out under that heading. This issue is quite up to the high standard set by the publication.

SPIRITUAL HEALING. Report of a Clerical and Medical Committee of Inquiry into Spiritual, Faith, and Mental Healing. Price, $0.30. London: Macmillan & Company, 1914.

THIS investigation was undertaken with the object of formulating a more clearly defined relationship and cooperation between ministers of religion and members of the medical profession in the treatment of disease. Their conclusions offer nothing new and give confirmatory evidence that what is called "Faith" or "Spiritual" healing is not different from mental healing or healing by suggestion. The report states that cures by these means are by no means unusual in functional disease, but it remains to be proven that any of these methods of healing have ever been effectual in the presence of actual organic disease.

Society Reports.

AMERICAN THERAPEUTIC SOCIETY.

Fifteenth Annual Meeting, Held in Albany, N. Y., May 29 and 30, 1914.

THE PRESIDENT, DR. HOWARD VAN RENSSELAER, ALBANY, IN THE CHAIR.

Friday, May 29—First Day.

Address of the President: A Study of the Therapeutic effects of Thermopenetration in the Treatment of Phthisis Pulmonalis.—DR. HOWARD VAN RENSSELAER'S address was on this subject. Many years ago, he said, a patient collaborator of statistics had recorded that in lesions of the mitral valve consumption was one of the rarest of complications, though he drew no deduction from this fact, observed, as the result of study, in a vast number of cases of heart disease. If we tried to trace out the relationship between cause and effect here, and if we considered for a moment the morbid anatomy which mitral disease produced in the lungs, we were struck by the fact that in mitral disease there is regularly a marked congestion of the lungs. By theoretical reasoning, then, it would seem that where there was an enormous amount of blood in the lungs tubercle were more readily destroyed, or were at least prevented from multiplying as they did in the anemic condition of rundown individuals. The obvious therapeutic indication from this reasoning would be to produce a congestion in the lungs as a means for combating the inroads of consumption, and theoretically what was wanted was not a passive, but an active congestion, caused by something which would directly heat up the lung as a whole, or any particular part of it desired, without producing a general congestion over a large area of the body. This it had been impossible to accomplish until the discovery of the many-sided effects of the high frequency current. At the tuberculosis camp of the Albany Hospital the employment of this current had given the best results of any special treatment which had been tried there. The patients had been impartially divided into three classes for treatment; those given the high frequency current, those given tuberculin, and those given no special treatment, which were called control cases. The benefits so far obtained from the high frequency current, in comparison with the other methods, were: (1) The ability to keep the patients longer in the hospital. (2) The greater increase in weight (five times greater), and the larger percentage of those whose weight was increased. (3) Of the discharged patients, 69 per cent. apparently cured or arrested, against 15.5 per cent. as the best of the other methods. A careful study of the large number of blood counts showed, in general, that in the cases which improved and got well both the red cells and the hemoglobin (which had usually been diminished) returned to normal, that the white cells decreased, and that the percentage of polymorphonuclears decreased, while that of the lymphocytes increased to normal.

The Acquisition of Tuberculosis.—DR. WILLIAM H. PORTER, New York, in this paper, said that it was established, so far as bacteriological research had advanced our knowledge, that tuberculosis is not, and cannot be, transmitted from the mother to the offspring *in utero*, and, consequently, that the disease is never inherited. In fact, a faulty nutritive activity was much less often inherited than was commonly supposed, but the perfect product, as it came from the uterus of the mother, rapidly degenerated when it had left the guiding hand of Nature and was entrusted to the too often ignorant and misguided parent or nurse. As time went on the nutritive vitality of the organism progressively deteriorated, local inflammations were excited, the proper soil was developed, and finally the non-tuberculous soil was successfully inoculated with tubercle bacilli and the lesions characteristic of true tuberculosis were developed. These anatomical changes had never been found until after the fourth week of extrauterine life, and the frequency with which they were afterward found increased yearly from five-tenths of 1 per cent. up to the fifteenth year, when the maximum of 30 per cent. was reached. Thus, it was proved conclusively that there was a well-founded theory regarding tuberculosis, which did not defy natural laws and was found to fit all conditions. While it was impossible to exterminate tuberculosis as completely as theory would indicate might be possible, it was still within the range of high probability to prevent the development of hundreds of thousands of cases every year. The accomplishment of this, however, was to be effected along the line of the prevention of a soil suitable to the growth of tubercle bacilli, rather than by over-strenuous efforts to prevent inoculation.

The Non-Operative Treatment of Tuberculous Glands of the Neck.—DR. ROBERT T. MORRIS, New York, said that in the past ten years there had been treated in the out-patient department of his service at the Post-Graduate Hospital considerably more than one hundred cases of this character without operation in a single instance, with the exception of such glands as were actually suppurating; and for these glands alone, leaving the remaining mass to be treated by some one of the conservative measures. The first of these he had tried was the injection of a 7 per cent. solution of iodoform in oil, according to the plan of Mosetig-Moorhof. In a number of later cases the use of the new high penetrating *x*-ray had proved the most effective treatment. More recently he had taken up the idea of adding the employment of tuberculin to the other resources, and he was now convinced that when this method was applied in the right way and for a sufficient length of time it was one of our most important resources against tuberculosis of any kind. Dr. Morris stated that for many years the plan of treatment he had pursued consisted of a very thorough removal of the glands *en masse*, with technical details quite perfect from the surgical point of view; but when in a number of cases he found there was recurrence of tuberculosis, and when he had lost a beautiful young girl from acute general miliary tuberculosis immediately succeeding upon operation, he had taken up the study of methods for non-operative treatment.

Volatile Substances Isolated from Tubercle Bacilli Cultures and Their Effects on Experimental Tuberculosis.—DR. ERNEST ZUEBLIN, Baltimore, said that some time since, at the Tuberculosis League Hospital in Pittsburgh, he had observed that every time that old tubercle bacilli cultures were destroyed a patient who helped as orderly in the laboratory complained of headache and general malaise. About the same time two friends of his, after sterilizing old tuberculin bottles in a closed room, had suffered for several days from chills, fever, headache and general malaise (constitutional tuberculin reaction). These observations had suggested experiments designed to detect any volatile substance escaping from tubercle bacilli cultures. His series of experiments with guinea pigs were described, and he stated that from the results of these it might be concluded that in tubercle bacilli there is contained a volatile substance of a lipoid nature chemically which possesses a much stronger penetrating odor than the original bacilli culture. Further investigations would be required to determine the presence of a volatile protein split product and other features. Having referred to certain recorded instances of acute intoxication resulting from the emulsifying or evaporation of tubercle bacilli cultures, he stated that, according to his interpretation, underlying the manifestations described there was not a simple intoxication, but that probably combined with this there was a hypersensitiveness, for the reason that the symptoms had seemed to be more pronounced in individuals giving a marked tuberculin reaction. So far, no definite explanation for the cause of these morbid manifestations had been offered. In concluding, the speaker said that there was reason for admitting the possible formation of volatile split products in growing tubercle bacilli, but to determine the exact chemical and biological properties of these bodies would require additional experimental work. The question also remained undecided whether the substances were akin to tuberculous toxin, and whether they were identical with those bodies which produced the hypersensitiveness. Although this investigation had not yet passed the experimental stage, it might in the future perhaps afford the basis of a treatment for tuberculous patients, in cases where a mild reaction was desired and where tuberculin could not be administered hypodermically.

The Topical Employment of Tuberculin in Certain Surgical Conditions: Hydrocele and Other Serous Effusions; Tuberculous Adenopathies; Chronic Sinuses.—DR. W. WAYNE BABCOCK, Philadelphia, said that in certain conditions the action of the tuberculin had proved very efficient. His first effort had been to combat local serous effusions, and his original intention was to first sensitize the patient to the bacterin and then, by

applying the bacterial derivative, to the affected serosa, to produce a rather violent but selective inflammatory reaction sufficient to cause endothelial exfoliation and plastic exudation. On injecting hydrocele with moderate doses of tubercle bacilli, however, he had found that the preliminary sensitization was usually unnecessary, as in many instances a violent local reaction promptly occurred. In cases in which no reaction followed the first injection, a second injection within the sac, made about for days later, was almost invariably followed by a sharp reaction. In every case thus far treated he had found that with the subsidence of the inflammation the hydrocele disappeared; so that patients who had resisted operative or chemical injection were relieved by this simple procedure. Serous effusions in bursæ, such as housemaid's knee, miner's elbow, etc., he had found to likewise react to the injection. In ganglion the secondary reaction might be so painful that simple rupture, as by the back of a book, or incision was to be preferred. In effusions of the larger joints he had not as yet tried the method, fearing that the secondary reaction might produce ankylosis. In recurrent forms of hydrothorax it was of value, but the dosage should be accurately determined and used with caution, as the reactive capacity of such a large serous surface was great. In two cases of advanced hydrocephalus he had injected the lateral ventricles without any evident reaction or improvement. In indolent tuberculous sinuses he had applied the bacillin emulsion topically, or injected it into the granulation tissue lining the sinus, with advantage. Patients with tuberculous cervical lymph nodes were usually very sensitive to tuberculin, but, in his experience, violent reactions had never been harmful, and had often been followed by marked local improvement. For indolent caseous glands a local reaction (most intense within the gland capsule) was safe, and tended to precipitate a rapid softening and expulsion of the infected pulp, or absorption. With glands not so far advanced in caseation, injections of tuberculin at a distant point might be followed by rapid absorption. In a fairly extended experience with tuberculin injections in tuberculous glands of the neck he had seen no evidence of a resulting dissemination of the disease. The technique of the injections in hydrocele and other conditions was described, and a number of illustrative cases were cited.

The Tuberculosis Home Hospital Experiment.—Dr. P. BRYNBERG PORTER, New York, said that his paper referred to a specially constructed block of tenement houses, the "East River Homes," built by certain philanthropic persons and placed at the disposal of the New York Association for Improving the Condition of the Poor. The recent report of the association, presenting a statement of the methods, results, and comparative cost during the first year in the combined home and hospital treatment of families made dependent by tuberculosis seemed to be worthy of special attention, as the record of a new and interesting departure. In the East River Homes, under the general direction of Dr. Linsly R. Williams, now deputy State health commissioner, twenty-seven families, seventy-nine members of which were tuberculous, lived in sanitary homes, had ample sunshine and fresh air, good and abundant nourishment, freedom from undue work and worry, reasonable segregation, skilful medical care, and constant nursing supervision. After giving some of the statistics of the home hospital during the year, Dr. Porter said it was the belief of the association that the remedying of social ills is just as urgent as the cure of the tuberculosis, because, without rehabilitation, the family would continue to live under abnormal conditions resulting in recurrences and fresh developments of the disease. In every instance the families received at the homes had been forced into poverty, and some were wholly destitute. At the time of admission the average income of the six families which were discharged as rehabilitated was $6.42 a week, while when they were discharged their average income amounted to $15 a week. The results observed in the tuberculous patients compared very favorably with those met with in the best sanatoriums, and it was worthy of note that no new cases of the disease developed in any of the families. The cost of the treatment, as thus conducted, had been found to be less than that of institutional treatment, and if the same beneficial results should be obtained in the next two years, the association believed that it would have pointed out the way to an advance in the control of the disease of the greatest practical value.

Dr. LINSLY R. WILLIAMS, Albany, N. Y., said that it had been a gratification to him to learn that some notice of the work of the Home Hospital had been included in the proceedings of such a representative body as the American Therapeutic Society. It had seemed to the projectors of the East River Homes that if some combination for the benefit of the entire family could be worked out it would be a great gain. The question of the complete control of the tuberculous patient was the marked characteristic of the experiment, and one important point was to see that he was not overworked. Having referred to some of the special features in the construction of the buildings, he stated that the classification of the cases had been interesting. The adults were divided into three classes: (1) those with definite clinical signs, with tubercle bacilli; (2) those with definite signs, without bacilli; (3) those without any active signs. Altogether, he believed that this was an excellent scheme—one which was very hopeful, and which might be utilized with advantage in other cities.

Dr. POTTENGER said he could speak only with high commendation of the home hospital treatment of tuberculosis which had been inaugurated in New York. There was no class in which so large a percentage of cures could be secured as the poor. Every city, he thought, must solve its own problems.

Digitalis in Chronic Diseases of the Heart, with Special Reference to the Advisability of Its Continuous Administration.—Dr. LOUIS F. BISHOP, New York, said that however much the scientific knowledge of digitalis might be advanced, the adaptation of the remedy must always remain a matter of art. Fibrillation of the auricle and very serious valvular disease were the most frequent examples of cases benefited by the use of digitalis over periods of months and years without interruptions. In both conditions, when broken compensation had recurred two or three times, and been restored by digitalis after days of waiting for the desired effect, a state of well-being, without these dangerous attacks, could often be maintained by suitable doses of the drug taken continuously. The amount required was more or less a matter of experiment. In chronic auricular fibrillation a good rule was to keep the pulse about ninety, while in valvular disease it was well to keep the tonicity of the heart muscle at such a point as to insure a minimum amount of shortness of breath. A third type of disease in which the continuous use of digitalis was often indicated was the later stage, or, as he was accustomed to call it, the "digitalis stage," of arteriosclerosis; when there was a tendency for the high blood-pressure to change to a low pressure falling below the line of compensation. The use of so powerful an agent required constant supervision, and every heart patient should be seen at least once a month. If a time came when the digitalis would not act, this was not because the heart had become habituated to it, but because it was no longer able to respond to the remedy. There was no such thing as a digitalis habit. There were many persons whose lives depended upon digitalis, and the drug might finally produce a true strengthening of the heart.

Parageusia and Its Treatment.—Dr. THOMAS F. REILLY, New York, said that the term parageusia had been coined by Varden, in 1889, to cover the complaint of bad taste experienced when there was no material in the mouth to account for it. He believed that most physicians had so long associated bad taste in the mouth with digestive disorders that they had been overlooking the fact that it is quite often an expression of diseased conditions other than those originating in the gastrointestinal tract. His attention had been first directed to the matter about a year ago while studying a group of patients who had various disorders of this tract associated with high arterial tension and the complaint of bad taste. Since then close questioning of all patients affected with high arterial tension with other evidences of nephritis had practically always revealed the presence of persistent bad taste. In the early stages of chronic interstitial nephritis the patient had this symptom only on rising in the morning, and in this it closely resembled the suboccipital headache so characteristic of early nephritis. In general, the prognosis seemed to be worse the more constantly the bad taste was present. In many instances this had been the only symptom complained of, and the speaker said he would suggest, as a working rule, that when a patient (particularly a person of forty-five or over) came complaining of persistent bad taste, a blood-pressure examination should be made at once. This sign often preceded the appearances of other symptoms by a month or more. In the cases associated with flatulence bromides acted better than anything else.

In those without flatulence, digitalis, either alone or with hydrochloric acid, had produced the best results. The vasomotors, such as nitrites, had not caused any improvement. In a few cases diuretics of the diuretin type had answered well. Next in frequency he had found this complaint associated with gallstones and cholecystitis, and in most instances the taste was described as bitter, like gall, though in a few cases it was like musty eggs. This gall taste had been practically always present in cases of drainage operation of the gall bladder, and it persisted as long as the bile drained. In several cases of catarrhal jaundice it had been noted from three days to a week before the appearance of the jaundice. In the bad taste observed in acute digestive disorders calomel, followed by rhubarb and soda, was generally all that was necessary; occasionally, hydrochloric acid answered better. In the bad taste noted in some cases of pulmonary tuberculosis during the latter part of the day, antipyretics of the coal tar series might be of service, though this was rarely the case. The bitter taste sometimes associated with coryza was occasionally relieved by adrenalin spray. Oftener there was a complaint of no taste, or that everything tasted the same. In acute rheumatic fever a disordered taste, bitter or acid, appeared to be present in about 60 per cent. of the cases. Kleiner had described this, and thought the salicylates relieved it. In two cases of pernicious anemia a persistent bitter taste had preceded the other clinical symptoms by six and eight months respectively. The bitter taste often complained of by decompensating cardiac patients was analagous to that observed in nephritis, and could usually be lessened by digitalis and diuretics. Patients with arteriosclerosis sometimes complained of an inversion taste—salty things tasting sweet. Having referred to the tastes observed to a greater or less extent in diabetes, hysteria, neurasthenia, pregnancy, gastric and duodenal ulcer, and cancer of the stomach and uterus, the speaker said that in disease of the central nervous system anomalies of taste occasionally occurred, and were often due to syphilis of the part. As the result of a year's close questioning of patients on the subject he was convinced that persistent bad taste in the mouth was a symptom of much importance, that it was always an expression of a serious toxemia, and that it was frequently of very great service in the early diagnosis of disease.

Some Problems in Genetics.—Dr. THOMAS E. SATTERTHWAITE said that as physicians we were especially interested in those phases of genetics which have to do with the propagation of normal human beings and of the abnormal through procreation. Though, for various reasons, the principles laid down by Lamarck, Darwin, Mendel, Galton, Davenport, and others, were not as applicable to human beings as to the lower forms of life, they might properly be utilized as bases for solving problems bearing on the legal regulation of marriage and the propagation of hereditary diseases. The history of the notorious "Jukes" family gave an instructive picture of the appalling consequences of improper matings. The history of the Kallikak family was even more instructive, as it contrasted the results of unfit with fit matings. Other somewhat similar family histories had been published, but even from the facts in these two the conclusion was plain that such calamities should in some way, if possible, be prevented, for the protection of society. Again, there were, as was well known, many infirmities which might be inherited, such as epilepsy, chorea, deaf-mutism, and various mental disorders. Karl Pearson, indeed, had claimed, from his study of statistics, that no less than 75 per cent. of all deaths were due to inherited diseases. Taking up some of the salient points concerned in heredity, the speaker cited the Mendelian laws, and said that these had been tested with reference to the feeble-minded by Goddard, as to the epileptic by Davenport, and as to insanity by Rosanoff. The last-named had further defined six possibilities with respect to the inheritance of either a neuropathic or normal constitution, in general accordance with his interpretation of Mendel's laws; and he had asserted that about two-thirds of all the patients admitted to insane asylums had inherited the neuropathic constitution. That the converse of this was true had been shown in a very striking manner by tracing the descendants of the distinguished theologian, Jonathan Edwards, as given by Walter. It was a matter of satisfaction that eugenics had taught us how a defective strain could be gradually minimized by selective matings, at least so far as physical and mental traits were concerned. The gonococcus might produce a systemic disease of great danger to life, while the spirochete of syphilis remained a powerful agent for infection even in the third stage; and it seemed as if the degree of infectivity in the venereal diseases, as with alcoholics and drug habitues, was proportionate to the morbidity of the one who transmitted the disease. Consequently, it was only reasonable that persons wittingly transmitting the venereal diseases should be amenable to the law. More than this, in extreme instances it was for the common good that such persons should be debarred from procreation. There could be no doubt that sterilization laws, if designed to prevent propagation by confirmed criminals, idiots, imbeciles, and rapists, indicated progress in the right direction. To what extent these laws had been carried out he had been unable to discover. They had certainly met with great opposition within the ranks of both the medical and legal professions. The question was a medico-legal one, and legislation in this matter must appeal to our intelligent judgment—must be reasonable in a legal sense. Many of our legislatures had also passed laws regulating marriage, and the public might be counted on to urge action in States where there were as yet no such laws. At present such legislation was to a large extent ineffectual, because the contracting parties could easily cross over into adjoining States or Canada; but eventually public opinion would be aroused by the evasion of the law, and would make its verdict felt in an unmistakable manner. Unfit marriages, as had been intimated, were not only a direct outrage to the offspring, but indirectly a crime against society, when as a result of them the unfit were born into the world. To make laws in conformity to present knowledge and requirements, and then to alter them in the face of new or special conditions, as might be desirable for the public good, was sound legislation. We should remember, however, that there ought to be no over-regulation of marriage. At all events, there should be no ill-considered, hasty, or unpractical legislation, such as the recent Wisconsin law, which had broken down from the weakness of its medical side. Indeed, all legislation in medical and sanitary matters should first be passed upon favorably by the medical organizations affected, in general or specifically, by the legislation proposed. Without being either a neurologist or a psychologist, he would venture to say, in conclusion: (1) While human eugenics is still imperfectly understood, there are certain principles bearing on the transmission of traits by propagation which are tolerably well established. (2) These principles should first of all be popularized, so that the adult portion of society will realize the importance of fit and the dangers of unfit matings. With an aroused public appreciation of these matters, appropriate legislation would sooner or later follow, and be made effective. (3) Uniform laws as to the regulation of marriage should be urged in every State, as well as laws to prevent the transmission of diseases by diseased persons. (4) While the motto *Salus populi, suprema lex*, is true, legislators should advocate only laws which will accomplish satisfactory results without an unreasonable curtailment of personal liberty. (5) There is urgent need of further researches in the field of eugenics, in order to clear up misapprehensions and so allay criticism as to its civic value; but, as this work would necessarily involve the services of special medical experts, expenditures of large sums of money, and unusual facilities, it should be relegated to the States or the general government, which could provide the men, money and opportunities and accomplish the most at the least expense. Reports from such sources would serve admirably for bases for the framing of appropriate laws, or for the amendment of those which have proved to be unsatisfactory.

Dr. EDWARD D. FISHER, New York, said that at present we were simply on the threshold of this matter. He would certainly question the correctness of the Mendelian theory, and we did not know enough to pass intelligently upon many of the legal measures [illegible] had been proposed; while if such statutes [illegible] enacted it would not be possible to carry them out as would be desired. As to sterilization, we could not get it applied in the State of New York. Practically, it would be very difficult to decide who should and who should not be sterilized. In this question of genetics there would always be two parties, the believers in heredity and the believers in environment.

Dr. SPENCER L. DAWES, Albany, said that undoubtedly all were in accord with Dr. Satterthwaite as to the desirability of improving present conditions, but personally he agreed to some extent with Dr. Fisher.

The facts recorded in the history of the "Jukes" family were very doubtful, and many of the statements of Rosenoff entirely unreliable. Of the patients in the New York State Hospitals for the Insane, no less than 45 per cent. were foreign born. Dr. Dawes then gave some further statistics of these hospitals.

Dr. CHARLES E. WOODRUFF, New York, said it was well known that in this country the Irish, who were of the blond type, were three times as prone to tuberculosis as the dark Hebrew. It was a fact that to-day there was not to be found a single representative of the Spartan or of the Athenian type, which had been established with so much forethought and care.

Dr. SATTERTHWAITE said that the figures given in the history of the "Jukes" family were not accepted by many. For this reason he had called attention to them, and endeavored to get at the motives which prompted their compilation. He thought they ought to be subjected to a rigid scrutiny by either the New York or national authorities.

Dr. WOODRUFF said he thought environment, not heredity, was the principal element to be considered. If the criminal had been subjected to good influences he would have been an orderly member of the community, though very likely deficient in intellect. He had an idea that it was the "good" families which were sending the most people to prison. As to the sterilization of those who were known to be liable to transmit imbecility, etc., he believed it to be a social necessity.

Dr. REYNOLD WEBB WILCOX, New York, said that what Col. Woodruff had stated about families was true. Those who had looked up the history of the "Jukes" family had selected the black sheep, and those recording that of the Edwards family had gone into it for the purpose of picking out the good members. Jonathan Edwards' first wife had been so bad that he finally had to divorce her; yet it was a fact that all the children of this bad wife were good and accomplished, while all the children of the second wife, who was of unblemished character, were mediocre. The criminals often came from the normal families in the community. The families of the four gunmen recently executed at Sing Sing were not criminals. There was one class of persons which had not been fairly treated, namely, the feeble-minded. It was rightly held that these unfortunates ought to receive the same care as the insane and the imbecile; yet it was a fact that in the State of New York only 4,000 out of the 19,000 in the State were now under custodial care. He believed that this society should recommend such legislation as would correct this condition.

In accordance with Dr. Wilcox's suggestion a motion was made and carried that a committee should be appointed to consider the advisability of the society's taking action in regard to the feeble-minded, and report at the next annual meeting.

Saturday, May 30—Second Day.

Diagnosis and Treatment of Diseased Conditions of the Cecum.—Dr. G. REESE SATTERLEE, New York, said that diseased conditions in the region of the cecum could often be distinctly classified and should be carefully studied before resorting to operation, as they were too frequently considered under the head of what might be considered a complication or sequela, appendicitis. Appendectomy, although it might be necessary, did not cure or even relieve the condition. When the cecum had a mesentery it was loose and freely movable, and had been termed "cecum mobile" or "loose typhlon." Many cases of dilated residual cecum and intestinal stasis gave symptoms resembling ulcer or adhesions of the duodenum, ulcer of the stomach, pyloric stenosis, and gallstones. The cecum had been aptly called the "second stomach," the close connection between the two being explained by their intimate relationship through the sympathetic system. Pain from lesions in the region of the cecum was often referred to the stomach, and vice versa. This close relationship was illustrated by the frequency of stasis in the stomach with dilated residual cecum, without any gastric, duodenal, or gall-bladder lesion. Close attention to these cases would often show the typical signs of cecal disease, a ballooned, tender cecum with thickened walls, and evidences of intestinal stasis. It was rare, he thought, to find this condition complicated by gastric or duodenal ulcer. A thorough *x*-ray examination of the whole gastrointestinal tract was necessary in every case. Radiographs with bismuth injection of the colon should be employed to prove apparent lesions in the cecum or colon. This was an excellent way to corroborate cecal stasis. Chronic appendicitis was often present, its symptoms overshadowed by the intensity of the other lesions. Constant tenderness over a large area to the left, with persistent constipation, indicated cecal disease rather than appendicitis, which usually gave a history of distinct attacks of pain, nausea, and vomiting. Symptoms of intestinal obstruction in this region pointed to adhesions or Lane's kink, intussusception or volvulus; which might sometimes be differentiated by the *x*-ray, though otherwise only at operation. The medical treatment of the dilated, ptosed, and sluggish cecum consisted in the relief of the ptosis by means of properly fitting abdominal supports, elevation of the foot of the bed to the point of tolerance, and massage and vibration with the object of increasing peristalsis and emptying the cecum and colon; with diet and hygiene and occasional doses of castor oil and colon irrigations with normal saline and ichthyol solutions. Russian mineral oil, taken regularly, had given excellent results. The free drinking of water was encouraged. Autogenous colon vaccines, made from cultures from the patient's stool, would relieve the autotoxemia and sometimes move the bowels. Among surgical operations which might be used was suspension of the transverse colon, which elevated the cecum. In conditions apparently leading to obstruction, short-circuiting, colostomy, or even ileostomy or colectomy were indicated. Plication of the cecum, with suspension of the cecum and, when indicated, of the sigmoid, had been successfully employed by others, and in a few instances by himself. The principal point was to do a thorough operation and leave no cause for hernia or obstruction. Diverticula and malignant and tuberculous growths should, of course, be removed. In cases with operation, as well as those without, autogenous colon vaccines had, in his hands, been of much service in relieving the autointoxication. Milk fermented by lactic acid bacilli was also a valuable aid. Included in the paper were reports of illustrative cases and many *x*-ray plates were shown.

The Medical Treatment of Intestinal Stasis.—Dr. REYNOLD WEBB WILCOX said that the fundamental cause of this conudition had become effective when *homo sapiens* became differentiated from the other primates and assumed the upright posture. From the standpoint of the physician the causes which could be remedied resolved themselves into four categories: 1. Insufficient peristaltic action of the intestinal wall. 2. Errors in diet. 3. Dryness of the intestinal contents resulting from deficiency in the secretion of the intestinal fluids, especially the bile. 4. Weakness of the muscles of the abdomen due to overstretching from various causes. Undoubtedly, partial stenosis of the bowel caused from within or without by the pressure of displaced organs, abdominal effusions, and peritoneal bands or adhesions interfering with the normal passage of fecal matter belonged to the surgeon. The diet should consist of substances which leave behind a considerable undigested residue, such as bran or agar-agar, to which should be added fruits and green vegetables. Agar-agar, to be effective, required, in addition, two grains of the extract of rhamnus purshiana every second night. In artificially fed infants care should be taken that the proteid content should be kept comparatively low and the fat be given in sufficient quantity, so that in later life the conditions favoring stasis and secondary toxemia might not be produced. Decomposing and fermentable foodstuffs and cold storage foods in general, and especially poultry and game, were to be avoided. Insufficient peristaltic action was to be combated by observing a regular time for evacuation, by the use of various "setting up" exercises, and, whenever possible, engaging in athletic sports. The use of 1/50 grain of physostigmine sulphate, with 1/30 grain of strychnine sulphate might sometimes be necessary. Dryness of the intestinal contents could be obviated by the use of several glasses of water at various times between meals, but the habitual taking of laxative mineral waters was to be avoided. From time immemorial oils had been employed, partly for direct laxative results, partly for action upon the bile, and partly for mechanical purposes. Of late the white Russian mineral oil had had considerable vogue as an agent for preventing intestinal putrefaction and absorption of toxic products and for softening the intestinal contents. In practice, the petrolatum liquidum of the pharmacopeia was very satisfactory. When administering it continuously it was well to give about once a week five or ten grain doses of calomel, followed by two drachms of Rochelle salt in artificial vichy water the next morning. It was a matter of experience that after a time a much smaller

dose of the oil was equally effective. High colonic irrigations, at a temperature of 112° F., administered once or twice a week by an expert nurse, might be substituted for calomel. Weakness of the abdominal muscles called for massage, manual percussion, and the faradic or induced static current. As to the various ptoses, it should not be forgotten that although they were merely isolated features in the etiology they required attention. After proper instruction and with careful attention to detail, suitable abdominal supporters, the Rose plaster belt, or the Gallant corset could be readily applied by the physician, with much benefit to the patient. Whether we might go so far as Lane would have us, and attribute to intestinal stasis and its resulting toxemia the many and diverse end results which we had hitherto regarded as distinct clinical entities, was not at present determined. If these radical opinions were finally accepted, a revision of our nomenclature would certainly be in order. Clinically, however, the results were undoubted. As to mechanical causes of stasis such as Jackson's membrane, Lane's kink, Morris's cobwebs, and Codman's drag, the physician believed these to lie well within the province of the surgeon, but, as even these structural defects might and did exist without giving rise to symptoms, he would agree with Morris in his statement, made at the last meeing of this society, that we should reserve operation for those cases in which really good and proper medical resources had been applied for a sufficient length of time without giving a high degree of relief.

Dr. Oliver T. Osborne, New Haven, Conn., said that among the students at Yale he saw a very large number of patients in the early stages of appendicitis or of inflammation in the region of the appendix, and that these cases were constantly on the increase. He had wondered whether they were due to athletics or to conditions incident to the students' being obliged to be in chapel every morning at 8:10. Their hasty breakfast usually consisted largely of oatmeal, taken with sugar and cream or milk, and they had no time to go to stool afterward. Chronic constipation developed, and this was no doubt the cause of the attacks he had observed.

Dr. Zueblin cited a case to show how extremely careful we should be in our interpretation of *x*-ray findings. In chronic constipation, simple medical treatment, he said, was often not sufficient, and he had found that vaccines might be of great service.

Dr. Babcock said it was a fact that many of these cases which could not be relieved by support, internal treatment, etc., might be favorably affected by means of vaccines. There was a class of old colon affections following typhoid fever which got well when they were treated with antityphoid vaccine. He had had two cases which were relieved by the use of colon vaccine.

Dr. Woodruff said that Dr. Satterlee's paper had shown still further the admirable results accomplished by vaccines. At the same time, we should not neglect to consider the cases in which they were liable to do harm. During the past two years his attention had been drawn to quite a number of cases of tuberculosis and other serious disease following antityphoid vaccination. He then cited instances of this, but stated that he had no wish to discourage the proper use of vaccines. They had done wonders, and he himself was advising them in suitable cases. In his own person, when he was suffering from general furunculosis, the results from them had been phenomenal. A vaccine would do exactly what the original disease would, and as to the length of the immunity conferred in any instance, this would depend upon the disease. If a disease itself produced a lasting immunity, we could rest assured that its vaccine would do the same. Thus, the Jenner vaccination, if properly done, undoubtedly protected the individual against smallpox for life. The immunity produced by antityphoid vaccine, he thought, would last at least long enough to enable a soldier to go through a campaign protected against typhoid.

Dr. Satterlee said he believed Lane was right in attributing ulcer and cancer largely to intestinal stasis, and that if we could eliminate intestinal conditions such as some of those he had described in his paper we would have a much smaller number of these affections to deal with. He thought the *x*-ray a very valuable aid to diagnosis. At all events, by means of it we could find out if a patient had enteroptosis, and these stasis cases could be divided into those with enteroptosis and those without.

Dr. A. Ernest Gallant, New York, said that if a person used bran regularly as an article of diet he would not have any trouble from Lane's kink. For the best results it was necessary to employ an absolutely pure bran, one sterilized by a temperature high enough to destroy any fungi.

Dr. Reilly said there was to be had a bread, composed largely of flaxseed and crushed cereals and producing the same effect as bran, which acts very satisfactorily.

Dr. Bishop said it seemed to him that in all the discussions on intestinal stasis he had heard the mechanical factors had been brought too much to the foreground, as though the intestinal tract were an inanimate tube. The intestine, by its peristaltic action, passed over the material in the tube and what we were dealing with in this condition was often not so much a physical obstruction as a matter of motility. In the treatment we should use a suitable dietary and also something for the relief of spasm caused by proteins.

Dr. Morris said that these patients were mostly neurotic. One of the worst possible cases of asthma he had cured by shortcircuiting.

The Use of Horse Serum for the Prevention of Hemorrhage in Nose and Throat Operations.—Dr. Clement F. Theisen, Albany, said that in a previous paper he had published a series of cases of hemorrhages after tonsillectomy and other operations in which, after the failure of other methods, the bleeding was controlled by injections of blood serum. In the series of cases on which the present paper was based the serum was used before operating, when it was expected that there would be an unusual loss of blood. The injections were given when from a history of cases of severe hemorrhage in the patient's family or of severe spontaneous hemorrhages in the patient himself such a result was to be anticipated, and they were given irrespective of the coagulation time before operating. It had been recognized that the coagulation of the blood was dependent on the action of thrombin, the so-called fibrin ferment, but Voetglin and Macht had recently isolated from the blood and the adrenal cortex a new vasoconstrictor substance, and it was quite possible that the action of the serum was due to this. In his own observations the coagulation time had been estimated by the coagulometer of Russel and Brodie, as modified by Boggs. In the eight cases of his series reported in the paper the average coagulation time before injection of the serum was 5.18 minutes and after injection 4.12 minutes, making an average decrease in coagulation time of 1.06 minutes. When the serum had been used before tonsillectomy in a subject of the hemorrhagic or hemophilic diathesis the operator left his patient with a feeling of much greater security. Judging by a search of the literature the much-talked-of danger of anaphylaxis was practically nil, when as in his cases only one injection of serum had to be used. Dr. Theisen said that no claim was made in his paper that blood serum was infallible. It had, indeed, been successful in his hands, but in some cases it might fail.

Dr. Osborne said that before using diphtheria antitoxin we should try to find out whether or not the patient was susceptible to horse emanations and the like.

Dr. Reilly said that various undesirable phenomena following the use of diphtheria antitoxin were sometimes improperly attributed to anaphylaxis. In the hemorrhages occurring in the course of chronic interstitial nephritis horse serum had not proved of any benefit.

Dr. Zueblin said that after the use of diphtheria antitoxin he had observed very severe and even fatal anaphylaxis. He would like to emphasize the desirability of employing the serums of different animals in the hemorrhages occurring in typhoid fever and other diseases. Personally he had used that not only of the horse but of rabbits, guinea pigs, and other animals. In the hemorrhages of typhoid he thought serum injections might prove of great service.

Dr. Stewart said he had had the opportunity of seeing some of the alleged cases of anaphylaxis after the use of diphtheria antitoxin and he thought it very unfortunate that there should be such a scare about the matter. Practically all the deaths from anaphylaxis had been due to lethal doses of the antitoxin. In France it was now customary to give a preliminary dose for the purpose of sensitization.

Dr. Rudolf said he had tried a great many agents for controlling hemorrhage, and he believed that the coagulation time of the blood was shortened more effectively by hemorrhage than by anything else. During the past winter he had had two cases which had illustrated this. One was a case of thoracic aneurysm and the other of abdominal aneurysm, and in the latter instance the patient had been bled three times, and on

each occasion the coagulation time of the blood had been greatly shortened. It was usually advisable to draw about fifteen ounces of blood.

Dr. THEISEN said that before using the serum he always tried to ascertain whether the patient was susceptible to horse emanations. Young subjects did not present this idiosyncrasy. His use of serum was for the *prevention* of hemorrhage, as a cautionary measure preliminary to operation, and he employed it only in cases where the history showed a predisposition to hemorrhage. His experience with the use of horse serum had convinced him that it was a most valuable addition to our resources for the control of hemorrhage. He agreed with Dr. Stewart that the published reports about anaphylaxis after diphtheria antitoxin had done much harm.

The Action of Pituitrin upon Acute Heart Failure and Uncompensated Heart Lesions.—Dr. ERNEST ZUEBLIN said that, impressed by the valuable results from pituitrin in obstetrical and gynecological work and by the marked physiological action of this agent upon unstriated and striated muscular fibers, he had undertaken a clinical study, especially in cases where, with a failing heart, immediate action became necessary. He gave reports of six cases and stated that from his observation, although two of them terminated fatally, it would seem that pituitrin was applicable in desperate cases.

Dr. RUDOLF said he was convinced that adrenalin and pituitrin exhausted the reserve power of the heart. In acute conditions there was plenty of reserve to draw upon, but such was not the fact in terminal cases, and such agents might kill very promptly. Therefore he believed that they should be used only in emergencies and when there was plenty of reserve power.

Dr. OSBORNE said he had used pituitrin frequently in the past two years and was convinced that it was a very valuable remedy. He would question the propriety of giving adrenalin and pituitrin in the same injection, as the former would quite overbalance the latter.

Inter- versus Intra-Menstrual Obstruction-Retention: A Résumé of 252 Cases, with Especial Reference to the Relatively Greater Importance of the Former in Causing Utero-Pelvic Disorders and Infections.—Dr. A. ERNEST GALLANT said that at the meeting of the society in 1909 he had presented a résumé of 185 cases of therapeutic drainage in uterine obstruction. Since that report, up to January 1, 1914, he had had occasion to drain sixty-seven additional cases, making a total of 252 cases treated by this plan. He gave the following summary of his views on this subject: 1. Normally the menstrual blood condenses in the passive uterus and escapes drop by drop or trickles from the os externum in a bright-red intermittent stream without the occurrence of malaise, pain, headache, or any kind of reflex manifestation. 2. Obstruction may be caused by fibrosis, cicatrization, flexure, or neoplasm of any kind affecting the cervical canal or involving the lower uterine zone. 3. Obstruction is primarily an intermenstrual condition which (a) causes retention of mucus, etc., within the uterus; (b) retards the outflow of menstrual blood; (c) shuts in the dangerous remnants after abortion and labor. 4. Obstruction excites the uterus to laborlike activity and brings about hypertrophy of the wall, enlargement of the cavity, increased weight, and an abnormal condition of the mucous membrane. 5. Obstruction during menstruation causes cramps, backache, headache, and other reflex pains; obstruction between periods forces infection into the tubes and results in peritonitis, tubal pregnancy, salpingitis, etc., and by thus obstructing the tubes is the most common cause of sterility. 6. Obstruction may be remedied by dilatation, drainage, replacement, pessary support, or suspension of the uterus. 7. Continuous efficient drainage can be secured only by the use of a drain which will permit the cervical mucus to pour into the drain, mingling with the secretions, and will prevent clotting and plugging. 8. To prevent recontracture of the internal os or return of anteflexion the drain must be of rubber, fenestrated or perforated, and must remain in position for six months or more. 9. Experience teaches that except for the removal of detached secundines or placenta curettage is unwise.

The Application of Some Muscular Tissues Adapted to Physiological Standardization.—Dr. F. E. STEWART and P. S. PITTINGER, Ph.G., Philadelphia, were the authors of this paper. At the meeting of the society last year they had presented the results of their investigations into the subject of standardizing ergot by means of its effect upon the isolated uterus. Their present report was largely devoted to researches looking to the standardization of pituitary extracts. They first employed the blood-pressure method which they had previously used in the case of epinephrin, but finding this unsuitable they had resorted to the isolated uterus method, as with ergot, and had found it even more satisfactory than in the case of ergot. Dr. Stewart said they had found pituitary extract a very powerful drug, and it was extremely desirable that there should be some standard of strength for it.

Auricular Fibrillation: Its Diagnosis and Treatment.—Dr. WILLIAM KIRK, Troy, N. Y., said that auricular fibrillation occurred in many forms of cardiac disease but was most common with mitral stenosis and in hearts which were the seat of cardiosclerosis. To the papers of Mackenzie we were especially indebted for the observation that in all cases of complete irregularity of the heart there is entire absence of sighs of the normal auricular contraction during diastole. The pauses between the beats bore no relationship to one another, and in this feature the irregularity stood in marked contrast to all other varieties. The second criterion consisted in the absence of a definite and continual relationship between the strength of the beat and the length of the pause, and a weak beat might succeed a long pause. The question had been raised as to whether the ventricular form of venous pulse could be recognized by means of the unaided senses. He believed that it could be a very large number, in fact the majority, of instances if note were taken of conjoined phenomena, and the first essential was the finding of an irregular pulse. In early and compensated cases, however, the pulsation was rarely recognized by ordinary means, for in such the visible pulsation was usually complex. Resort then had to be made to the graphic method, and by this a venous tracing might often be secured when no venous pulsation could be seen. The general practitioner unfamiliar with the instruments of precision used in the graphic method might recognize the presence of auricular fibrillation ordinarily from a persistent irregular pulse, the rate of which was at or about 120 (which would be almost positive evidence for the diagnosis), and the occurrence of a deficit between the rate of the apex and the radial pulse—a characteristic met with in practically every untreated case. In the treatment the first consideration was the removal of the exciting cause, such as overwork or digestive trouble. Digitalis acted as a specific in a very large proportion of cases, and the guides which rarely failed the physician as an index for the amount of the drug required were the irregularity of rhythm and rate in the heart's action and the deficit between the apex beat and the radial pulse. The choice of a preparation was, in his opinion, largely a matter of taste, provided the one used was known to be effective. Personally he believed there was none superior to the tincture, and he had found that supplied by good manufacturers remarkably constant in quality. It had been his custom to employ a standardized tincture or fluid extract, or the fresh infusion of the green leaves. When the pulse had been reduced to 60 or 70 and the apex beat coincided with the rate of the radial pulse it was wise to discontinue the digitalis for a time and then begin again with smaller doses, or else to continue with smaller doses in order to enable the heart to do its work with the greatest efficiency. The following indications were sufficient to warrant either the discontinuance of the drug or the diminution of the dose: the occurrence of severe headache, with or without nausea and vomiting; the dropping out of ventricular systoles (partial heart block); the occurrence of bigeminy which seemed to be continuous.

Dr. SATTERTHWAITE said that auricular fibrillation was not an uncommon condition. He agreed with the author of the paper that generally it could be recognized. The graphic method showed it absolutely. This method was the one thing which had restored the sphygmograph to use. The latter had been discarded because it did not show the different forms of valvular disease. It did, however, show the difference between the cardiac and the radial pulse. As regards treatment the only point on which he disagreed with Dr. Kirk was concerning the preparation of digitalis to be used. With its glucoside, digitalin, we did not have the gastric disturbances so often caused by the infusion. A good tincture was satisfactory, but unfortunately the tinctures supplied by the drug houses varied greatly. As to the prognosis the patient was kept in just the position in which the physician held him. The diagnosis having once been made the patient should be made to understand that he stood upon the brink of a precipice

and that he would die unless he obeyed instructions implicitly. He was of the opinion that in these cases the trouble had its seat in the myocardium, believing that there was a lithemic condition and undoubtedly a deposit in the heart. The great difficulty was that patients were apt to get tired of the treatment. They intermitted their medicine and they went off suddenly.

Dr. BISHOP said that as regards polygraphic tracings and their interpretation there were three points worth noting: 1. A polygraphic curve had nothing to do with a mathematical curve; it might be symmetrical or might look like a crooked line; one kind was just as good as the other for making a diagnosis. 2. The curve was simply a record of something which was taking place. 3. The important part of it was the beginning of the up-stroke; taking careful note of this we might disregard the respiratory curve, the shape of the curve, and everything else.

Dr. STEWART said that in digitalis there were at least four glucosides and some other principles about which at present we knew nothing. He thought digitalin ought to be standardized.

Dr. WILCOX said that the preparation of digitalis which best showed the action of the drug, as originally described by Withering, was the infusion. The chemistry of digitalis was extremely obscure. As to the sphygmograph he had made over 20,000 tracings with it. He had also made a special study of the six drugs of the digitalis group. There was in digitalis a substance which was centrally emetic, though the glucosides caused less gastric disturbance than the infusion. A practitioner, he thought, would get the best results from that preparation which he knew most about.

Dr. RUDOLF said that the manner in which digitalis acts in these cases certainly could not be interpreted in pharmacological terms. In the human subject its vagus action did not appear to any extent when the drug was given in physiological dose. In fibrillation it had a peculiar action on the ventricle, so that the latter responded to this storm which rushed down from the bundle of His.

Dr. REILLY said that sometimes digitalis seemed to fail, and we had another drug apocynum, which might then prove of service. The eclectics called it the "cardiac trocar." It was very irritative to the stomach, but did not act satisfactorily when given by the rectum.

Dr. KIRK said that ordinarily he had used the tincture and also the infusion of digitalis. The general value of the infusion had been impressed in the teaching of both the elder Janeway and his son. As to the glucosides not causing gastric disturbance it had been shown that some emetic effect was produced by any preparation of digitalis representing its pharmacological properties by reason of the central action of the drug. The great question in digitalis therapy was, he thought, in regard to the chemistry of the drug. He believed the fat-free preparations would produce more or less gastric irritation on account of their central effects. As to apocynum he had employed it with very good results when the patient did not have emesis.

Dr. WILCOX said it certainly had been conclusively shown that digitalis and its preparations had a central emetic action. The amount of the gastric irritation caused was a matter of degree, and less nausea resulted from the fat-free preparations than from the others.

Election of Officers.—The following officers were elected for the ensuing year: *President*, Dr. Francis M. Pottenger, Monrovia, Cal.; *First Vice-President*, Dr. Robert T. Morris, New York; *Second Vice-President*, Dr. Spencer L. Dawes, Albany, N. Y.; *Third Vice-President*, Dr. J. Madison Taylor, Philadelphia; *Secretary*, Dr. Lewis H. Taylor, Washington, D. C.; *Treasurer*, Dr. A. Ernest Gallant, New York; *Editor of the Transactions*, Dr. P. Brynberg Porter, New York; *Members of the Council*, Drs. Howard Van Reusselaer, Albany, N. Y.; Thomas E. Satterthwaite, New York, and J. Blake White, New York. Next place of meeting, San Francisco, Cal.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held May 19, 1914.

DR. JOSEPH C. ROPER IN THE CHAIR.

THE contributions of the evening were from the Second Medical (Cornell) Division of Bellevue Hospital.

History and Autopsy of a Case of Necrotic Bronchopneumonia Probably Due to a Streptococcus.—Dr. ROLFE FLOYD presented this report. The patient was a girl, 19 years of age, who at the time of admission to the hospital gave a history of having had an unexplained fever of two or three weeks duration. Examination showed a palpable spleen, no leucocytosis, and no localizing symptoms. On the fifth day in the hospital she was seized with a violent paroxysm of coughing and raised blood-streaked sputum. A patch of dulness, broncho-vesicular breathing, and subcrepitant râles were found at the angle of the right scapula. The patient continued to suffer from pulmonary symptoms until the time of her death, 58 days later. She had a persistent and violently paroxysmal cough with large and increasingly tenacious mucopurulent, and sometimes bloody, sputum without gangrenous odor. Eight examinations failed to show the presence of the tubercle bacillus, but toward the end of the illness a hemolyzing streptococcus was twice isolated in large numbers. The pulmonary signs were those of an extending bronchopneumonia with cavities later on. The temperature ran an irregular septic course. The pulse and respiration gradually rose. The leucocytosis varied, the maximum being 22,000. Blood cultures were negative. The autopsy, performed twenty-two hours after death, showed that the only important lesions were in the lungs. The upper right lobe was consolidated and its upper part honeycombed with small cavities with sloughing walls, and containing dark mucopurulent exudate. They all connected with bronchi. The general consolidation had a peculiar gelatinous appearance with small white spots in it. The right, middle and lower lobes showed many peribronchitic zones of consolidation. Elsewhere they were congested and edematous. The left upper lobe was in the same condition as the right with a single cavity under the nipple. The left lower lobe was like the right lower lobe. The bronchi were inflamed throughout their entire length and filled with mucopurulent exudate. Under the microscope there was found necrosis of most of the small bronchi, varying in degree, and sometimes invading the adjacent lung tissue, with resulting cavity formation. When there was no necrosis in the bronchiole the walls were densely congested and infiltrated with pus and their lumen was full of exudate. Some of the lung tissue showed ordinary consolidation, but extensive areas showed embryonal alveoli lined with cuboidal epithelium scattered through a loose areolar basement substance infiltrated with pus and round cells in foci. In all three typical miliary tubercles were found, but many sections stained for tubercle bacillus failed to reveal any.

DR. WARREN COLEMAN said that the chief interest in this case centered around the question of diagnosis. The patient had been in his service and had been followed very carefully; the diagnosis ultimately lay between tuberculosis and a bronchopneumonia of unknown origin. They could not discover tubercle bacilli in the sputum, yet cavity formation strongly suggested tuberculosis.

DR. ALFRED MEYER said that in about 1882 the medical profession was responsible for getting up a public meeting at Cooper Union because of the dirty streets of the City of New York, which were held responsible for the many cases of pneumonia which developed pulmonary gangrene or abscess in place of resolving. A similar case he saw but a few days ago at Mt. Sinai Hospital. The patient was moribund when seen by him. This was a case of lobar pneumonia involving the left upper lobe with beginning gangrene. The importance in this case was in recognizing the unusual physical signs presented. The area of dullness, almost flatness, extended beyond the ordinary pulmonary area, running across the episternal notch to the other side. In other words, there was a triangular substernal dullness, below the episternal notch, the sides of the triangle measuring about 1½-2 inches. The patient died shortly after. The autopsy showed that he had an enlarged lung which greatly encroached upon the mediastinum. The pathological examination was made a little less than two hours after death and the pathologist reported as follows: "The entire left pleural cavity was completely obliterated by friable adhesions. From apex to base the entire left lung, with the exception of a small area near the anterior edge, in both upper and lower lobes, was completely solidified and *very voluminous*. On section, the entire lower lobe and the anterior part of the upper lobe presented a very granular appearance and were brownish-gray in

color (gray hepatization). On section about two-thirds of the upper lobe consolidation was seen to be very much softened, and consisted of reddish-brown, semi-gelatinous material. It gave off a peculiar pungent odor. The right lung showed a small wedge-shaped area near the apex, the size of a walnut, which was in in the stage of red hepatization. There were also a few small calcified areas at the apex. The posterior part of the lower lobe showed moderate congestion and the entire right lung presented the appearance of an extreme degree of emphysema."

The Effect of the High Calory Diet on the Fecal Flora in Typhoid Fever.—Dr. JOHN C. TORREY presented this paper which was based on a study of the fecal flora of a series of typhoid cases, placed on the Coleman high calory diet. The following points were among those established: The intestinal flora, as revealed by an examination of the stools soon after the admission of the patients to the hospital, was not specific and obligate in type, but exhibited the same variations as would be encountered in a series of supposedly normal individuals. On a diet consisting of a daily average of 50 to 100 grams of protein, 75 to 100 grams of fat, and 250 to 300 grams of carbohydrate, including lactose, the intestinal flora tended to become converted into a fermentative, non-indol producing type. The degree of transformation depended largely upon the type of flora which was present at the onset of the disease. With a markedly putrefactive flora the change might not extend further than the elimination of the obligate putrefactive bacteria and a moderate development of the acidophilic types; while with a more favorable initial flora the change might be of so radical a type that the stools came to resemble those of the normal nursling in the dominance of the *B. acidophilus* and even to the presence of the *B. bifidus*. Such a flora was an obligate fermentative one and was not capable of forming indol and similar supposedly toxic products, under ordinary circumstances. Patients exhibiting an initial fermentative flora tolerated the high carbohydrate diet much better than those with a flora of putrefactive tendencies. In these patients, too, the disease ran a comparatively mild course. The typhoid bacillus was isolated from the stools of these patients on a high calory diet less frequently than has been reported in other series of cases in which the feeding has been less liberal.

Dr. WARREN COLEMAN said he wished to call attention to two points. This work furnished further evidence of the beneficial effect of feeding typhoid patients with large amounts of carbohydrates. Also the results explained why, occasionally, patients could not be successfully fed. From the very beginning of this work it had been found that the average patient could take up to 3,000, 4,000, or even 5,000 calories a day; exceptionally cases were met with who could not go beyond 1,200 or 1,500 calories without disturbances of the alimentary tract. Kendall's work upon the flora of the intestine in other diseases have suggested that the cause of this was to be found in a diminution of the acidophiles—Dr. Torrey's work had demonstrated that this was the case.

The Respiration Calorimeter in Nutritional Work.—Dr. GRAHAM LUSK presented this paper. He stated that the methods and results of the experiments of Lavoisier published in 1789 were the beginnings of modern work upon nutrition. Rubner first demonstrated that the heat produced in the organism was entirely due to the oxidation of carbohydrate, fat, and protein. Atwater who had worked in Voit's laboratory in association with Rubner organized the forces which produced the first respiration calorimeter for use with man. In this he received the invaluable assistance of Rosa. This work was now being continued by Benedict in Boston. About five years ago Williams began the construction of an Atwater-Rosa-Benedict respiration apparatus for the physiological department of the Cornell University Medical College, for use in determining the heat production of dogs or babies. Williams added devices which improved the sensitiveness of the apparatus. The results were so satisfactory, that the writer, after obtaining from Benedict the verbal statement that he did not desire to construct a calorimeter in a hospital, sought funds for the construction of such an appartus for use in Bellevue Hospital. The income of the Russell Sage Institute of Technology was obtained for this purpose. The apparatus cost $5,000 and each experiment cost about $100. The principle involved was that the *basal metabolism* as measured by the heat production in the morning, twelve to eighteen hours after food ingestion, was constant, and almost the same in adult individuals of the same weight and of normal shape. In the same individual, Loewy stated that the basal metabolism might not vary 10 per cent. during a period of 20 years. The basal metabolism was increased by work and by food ingestion. The factor of work was excluded by the patient lying quietly upon a comfortable bed. It was the province of the apparatus to determine how far the basal heat production and therefore fuel need of the organism departed from the normal under the influence of disease, how the ingestion of food affected the heat production in disease, and how therapeutic measures might modify the intensity of the pathological disturbances. Dr. DuBois would present some of the observations which he had made along these lines.

The Respiration Calorimeter in Use in the Clinic.—Dr. EUGENE F. DUBOIS presented this communication in which he stated that for therapeutic and diagnostic purposes it was frequently necessary to determine exactly the energy requirement of certain patients. Knowing the total metabolism or total heat production one could regulate the amount of food so that the patient would neither gain or lose weight or body tissue. In this way one could maintain the proper nutrition without overtaxing the stomach, the kidneys, or perhaps the oxidative powers of the tissues. The method at present in use was to weigh the man and to calculate the basal or fasting heat production of a normal man of the same weight, using a figure between 27 and 22 calories per kilogram per day. To this would be added 10 per cent. for the increase in metabolism caused by the ingestion of food, 10 to 20 per cent. for the activity of the patient in reading and sitting up in bed, and perhaps an added percentage if the patient were suffering from some disease which increased the metabolism. This method was of necessity inaccurate because it involved so many guesses. A very great amount of work on the normal heat production and the influence of various factors had been done by many observers. A closer study of the individual factor was made possible by the perfection to which the respiration calorimeter of the Atwater-Rosa type had been developed by Benedict and by H. B. Williams. The respiration calorimeter of the Russell Sage Institute of Pathology was situated next to the small metabolism ward of the Second Medical Division of Bellevue Hospital. It resembled Benedict's bed calorimeter but was somewhat larger to give the patient more space. In spite of its large size, it was accurate within 5 per cent. in hourly periods and within one to two per cent. when the observation was prolonged to three hours. This accuracy had been tested repeatedly by alcohol checks. When a known amount of alcohol was burned within the calorimeter, the oxygen consumed, the carbondioxide, the water, and the heat produced, as calculated from the chemical composition of the alcohol, agreed almost exactly with the actual measurements. Even more striking was the fact that in the total of the observations so far calculated the methods of direct and indirect calorimetry agreed within 1.4 per cent. The method of direct calorimetry depended upon the measurement of the actual heat of radiation, conduction, and vaporization. The method in indirect calorimetry depended upon the determination of the carbondioxide produced and the oxygen consumed. Knowing these two factors and the nitrogen of the urine, it was possible to determine the grams of carbohydrate, fat, and protein actually oxidized. These two methods of measuring the total metabolism agreed within five per cent. in three-fourths of the observations, and would agree even more closely were it not for the difficulty in measuring the average temperature of the body. In hourly periods the method of indirect calorimetry was more accurate. The experimental procedure was simple. After a few trials in order to become accustomed to the calorimeter, the patient, on the morning of the observation was placed in the calorimeter without having had breakfast. The box was sealed at about half-past ten; the observation began at eleven, and was finished by one o'clock. Longer observations were made when the effects of different foods were being studied. The box was maintained at a constant temperature and the ventilation was good. The patients refused to believe that the calorimeter was not of therapeutic as well as of diagnostic value. This was probably due to the fact that of the twenty-five patients who had been in the calorimeter there was not a single one who was not better now than before he was in the calorimeter. This was largely the result of good fortune aided perhaps by careful dieting in accordance with the information ob-

tained from the calorimeter. It was easy to determine the total metabolism in a group of cases, but it was difficult to know just how to compare them with normal individuals. The heat production of a number of normal men had been determined and had been added to the group results obtained by Benedict in his calorimeter. If the subjects were arranged according to weight and the results were expressed in terms of calories per kilogram per day a curve was obtained which fell steadily as the weight increased. On the other hand, if one expressed the results in calories per square meter of body surface, the average would be the same for persons of different weights, although the different individuals might vary 10 per cent. above or below the average. It was for this reason that they compared all the results with the normal average figure of 34.4 calories per square meter. The disease studied most thoroughly was typhoid fever. Working with Dr. Warren Coleman, he had been able to continue the observations begun with the small respiration apparatus and to study in greater detail the fasting metabolism and the effects of large amounts of food. The fasting metabolism in typhoid fever might be 40 to 50 per cent. above the normal and the metabolism after large amounts of carbohydrates and protein was scarcely raised at all, whereas in normal individuals there was an increase of from 10 to 17 per cent. caused by the same amount of food. Seven patients with hypo- and hyperthyroidism had been studied with particular interest since it had long been known that the activity of the thyroid gland was perhaps best measured by the total metabolism. In one cretin, 36 years of age, with the development of a child of eight years, the metabolism was only 75 per cent. of the normal, and rose to the normal after the administration of thyroid extract. In a patient with exophthalmic goiter, the metabolism was at first 180 per cent. of the normal, falling to 160 on treatment consisting of rest and overfeeding. In a young woman with what seemed to be a moderately severe case of exophthalmic goiter the metabolism was 192 per cent. of the normal, falling to 160 per cent. after the ligation of all the arteries. A few observations had been made as to the influence of blood pressure, anemia, and rest in bed on the total heat production. It had required eighteen months work and 140 observations to obtain the present results. It was therefore obvious that it would be the work of years to determine the influence of all the varied factors which presented themselves in the complex picture of disease.

The Treatment of Diabetes Mellitus with Cultures of Bacillus Bulgaricus.—Dr. PHILIP HOROWITZ presented this communication. He declared that whatever the etiology or the pathology of diabetes might be its treatment was a very important subject, both because the disease was on the increase, and because so much could be done for it. It not only was not a hopeless condition, but was positively curable in the majority of cases. The mode of treatment which he used was entirely different from the forms adopted up to the present time, and because it was so little understood and so many errors were made he had presented this paper. After reviewing the various forms of treatment advocated for diabetes up to the present time, and they were by no means few, Dr. Horowitz related that about three years ago he had accidentally discovered that by using the cultures of *B. bulgaricus* to overcome a severe autointoxication coexisting with diabetes in a member of his own family, that as the autointoxication became less the percentage of glucose in the urine was reduced. Within a period of ten weeks a condition which had appeared very serious and grave was apparently overcome. This condition was not merely a transient glycosuria of the alimentary type, but one associated with a high sugar index, acidosis, marked loss of weight, and drowsiness almost verging on stupor. With these there were also polydipsia, polyphagia, and polyuria. At the end of about fifteen months he had reported three other cases in the MEDICAL RECORD, March 9, 1912. Since that time he had treated a series of 102 cases; in 52 of these the sugar had been entirely eradicated, and most of the patients were now on a fairly normal diet; four cases had had the sugar reduced to traces, and 39 were improved. Some of the latter cases were still under treatment, and many of them would be cleared up before long. Out of the remaining seven one did not improve at all, no matter what was done; two died of nephritis; one of cancer of the bladder; two of pneumonia, and one of tuberculosis of the vertebral column, subsequent to an injury. One of the series was under ten years of age, five were under twenty, eight between twenty and thirty, eleven between thirty and forty. Fifty of the cases had a sugar index between three and nine per cent. Forty-seven were complicated by acidosis. In seventy of the cases there was an active autointoxication as shown by the presence of indican. The average length of treatment was about three months, but it varied between two weeks and fifteen months. The treatment as Dr. Horowitz employed it consisted of two parts: First, the use of the cultures of the *B. bulgaricus;* and, second, a proper and well regulated diet. He had experimented with each of these measures separately and was successful with neither when it was used alone. The action of the *B. bulgaricus* was twofold. First, it was a corrective for the autointoxication which was almost universally present; and, second, in correcting and aiding carbohydrate metabolism. The *B. bulgaricus* by its power of secreting lactic acid interfered with and slowed down the carbohydrate metabolism. The essayist said he was absolutely convinced that diabetes was caused by a protein toxin, or toxins, formed in the intestinal tract, or possibly in the entire alimentary system, which interfered with the proper function of the liver and pancreas, and possibly with all the organs having internal secretion, and also had some bearing on the proper combustion of sugar. The dosage of the culture depended on the degree of autointoxication and on the severity of the diabetic condition. In simple cases of diabetes which were uncomplicated by acidosis and with a daily output of 16 grams of glucose or less, the dose was five to seven c.c. of the culture diluted in a little water one-half hour before meals and on retiring. In cases secreting more than this amount he gave 16 c.c. three times a day one-half hour before meals and on retiring. Where the output of sugar was low, but complicated by acidosis, he used large doses of the cultures, as lactic acid to a certain extent prevented the formation of acetone. In cases having a pronounced autointoxication with marked indicanuria, better results were obtained by giving a culture containing both the *bulgaricus* and the *Glycobacter peptolyticus* of Metchnikoff. In some cases which did not respond to this treatment it was supplemented by colonic inoculation of the culture. Full doses of the cultures must be continued for some time after the sugar had disappeared from the urine. He had found that it was not safe to reduce the dose for at least from four to six weeks after repeated analysis showed that there was no sugar in the urine. Then, if no sugar recurred, one dose at a time was withdrawn, until finally it was discontinued. Every man who had any experience in the treatment of diabetes would now concede that the strict carbohydrate free diet was a thing of the past. More diabetics died from acidosis and coma brought on by too strict diet than from the ravages of the disease itself. There was no definite stereotyped diet that was applicable to every case. The diet set forth was only a general one and must not be considered proper for every case. All cases should receive some form of carbohydrate. Every case of his received either rice, oatmeal, or wheatena. The cereal must be well cooked. From 45 to 90 grams of the cereal was given every day, preferably for breakfast, unless there was severe acidosis, and then it was given with every meal. He also started the patients with 60 to 90 grams of toasted white bread, toasted dry to eliminate as much moisture as possible. This was preferable to most diabetic foods. The bread should be baked at home, using only wheat flour, yeast, and a little salt. As the percentage of sugar decreased, the amount of bread was increased. This must be done very gradually, and one must be guided by the tolerance of each individual case. Four to six eggs a day were permitted, the preparation of which depended on the urinary findings. In cases with marked indicanuria it was best to have them boiled at least twenty minutes, or poached hard, for the reason that in this form they produced less putrefaction in the bowels. Milk was permitted only in such quantities as were needed to whiten tea or coffee, and to loosen up the cereal, but not over four ounces in all. He did not permit butter or fats in any form in cases complicated by acidosis. All cases that excreted acetone and acetoacetic or diacetic acid, were made worse by the use of fats, especially butter and cream, as these were an added source of putrefaction and a source of danger, as they increased the formation of beta-oxybutyric acid and acetone. Meats were permitted in some form unless there was an especial contraindication, but fried or roasted meats and rich gravies were not permitted. In cases complicated by a chronic diffuse nephritis only the white meat

of chicken was allowed. Only plain simple broths were permitted, omitting such vegetables as contained sugar. Vegetables containing sugar and those not easily digested were proscribed, but spinach, string beans, celery, raw and stewed, lettuce without dressing, asparagus with a small amount of butter were permitted. Vinegar and other acids were not permitted. Of fruits, grape fruit alone was allowed at first, but as the case cleared up sour orange was added very cautiously. Apples were not allowed until the urine was sugar free for some time. Fish and shellfish were not allowed at first as they were apt to increase intestinal putrefaction. Alcohol was not permitted in any form in the beginning, but when the case had cleared up a little Scotch whiskey, or dry sherry, or claret, might be given. Good mineral waters were permitted. Very few drugs were used and only those indicated in the particular case under treatment. Attention to the bowels was important. It was also important that not only the kinds of food but the quantity should be carefully regulated, and that proper attention should be given to the subject of exercise.

Dr. T. STUART HART believed that Dr. Horowitz, in announcing the discovery of a cure for diabetes (something which had never yet been accomplished in spite of the earnest work of many master minds over a period of many years), had made a claim which could only be accepted when the most conclusive evidence had been presented. This evidence Dr. Horowitz had not afforded. The time allowed to Dr. Horowitz might have been insufficient in which to present his proofs; only one case had been cited and in this both the time of observation (3 months) and the facts as presented did not warrant the statement that a cure had been secured. Judgment on this method of treatment should be reserved until detailed facts and evidence which carried conviction should be presented.

Dr. GRAHAM LUSK said that lactic acid fermentation might lead perhaps to conditions in the intestines which were beneficial to digestion. But lactic acid was absorbed and converted into glucose in the diabetic organism. There was much evidence which showed that lactic acid when absorbed by the normal organism must be converted into glucose before it could be oxydized. The historical introduction of the paper was interesting but this very history showed that so many cures had been advocated for diabetes that any new method of treatment must be based on sharply defined evidence before being accepted.

Dr. GEORGE REESE SATTERLEE said that he had tried lactic acid cultures in diabetes and in one or two cases he noted peculiar results. In one case although the sugar cleared up from the urine, the diabetes was not cured. In another case there occurred an obstinate constipation. This ultimately resulted in appendicitis and death. In one or two other cases also the results were not at all good.

Dr. MAURICE PACKARD said that he was very much interested in the so-called treatment of diabetes by the lactic acid bacillus for various reasons, but one of the many was that it was so well advertised. Not only did dispensary patients tell of their treatment by the bacilli, but private patients as well, either spoke of it as having been tried, of course with no results, or asked a number of questions as to its efficiency. He had tried it in a number of instances, with apparently no results. At present there were four patients at the Gouverneur Hospital, in the service of Dr. Huddleston, Dr. Henderson, and himself, whose sugar toleration had been worked out by Dr. Henderson and to whom lactic acid bacilli culture had been given, to see whether it increased the tolerance; the case had been under their treatment but a very short time, about ten days, and no result had yet been noted. He had also had a number of cases treated by Dr. Horowitz, personally, and one of these patients, probably reported cured by him, had died of coma in the Polyclinic Hospital three weeks ago.

Dr. PHILIP HOROWITZ closed the discussion. He said that some of the cases dated back two years or more and, with the exception of two or three cases, they were sugar-free at the present time and were on a nearly normal diet except that they did not take sugar. With regard to constipation, a point brought up by Dr. Satterlee, he found that about 90 per cent. of the patients suffered from constipation when they presented themselves for treatment. In all these cases there was a stasis of the colon and the cecum was out of place. The constipation therefore resulted from a mechanical process.

Miscellany.

Medical Certificates.—Sir John Collie states that medical certificates in legal cases should always be given with great caution. What should one do when asked to examine an injured person by both employer and employee, or by two parties to a suit in an action at common law? There is a general impression that, having given a certificate to one side, it is disloyal— indeed, dishonorable—to fish, as it were, on both sides of the stream, and furnish a report to what the lawyers call the "other side." This attitude assumes a very low standard. If one has given a certificate for a plaintiff which exaggerates his injuries, or if acting for the defendant, one has given a certificate minimizing what exists, obviously it would be impossible to report on the case to the opposite party to a suit. Medical men are not partisans in law suits; unlike the attorney, they have no "other side" to consider. Solicitors and barristers are paid to make the best case they can for their client. The doctor certifies facts as found, or should do so. There is, therefore, no reason whatever why a certificate should not be furnished to both parties and a fee charged to each. Of two things, however, one must be scrupulously careful. First, the facts must be presented in exactly the same way in both instances. Indeed, the safest plan is to make the second report a copy of the first. Secondly, both parties should be acquainted with the fact that such a duplicate certificate has been issued. Loyalty demands this. It is always advisable to retain an exact copy of all letters and reports on medico-legal cases.—*British Medical Journal.*

Large-Sized Tires.—H. Massac Buist points out that one of the lessons learned at the recent Grand Prix race on the Lyons circuit is that what the larger sized tires take off in speed is more than saved by what is gained in their extra wearing qualities; there is in these tires more material to be worn away before the time comes to change. Translated into terms of the private motorist's position, this means also that, within reason, it is more gainful to use large than small tires. On the other hand, when employing large section tires on small rims, the motorist must be careful to keep an eye on his pneumatics. Thus if he allows them to get slack he has that amount more twisting action of the walls when taking corners, and that extra liability temporarily to displace the bead, which in flying back may perchance nip the tube. On the other hand, he must not go to the other extreme of keeping tires too hard in summer weather. Many motorists remember to their cost the hot summers when tires burst on account of being kept under too high pressure in hot weather. We are still at the period when the individual motorist has as much to gain from carefully studying tires as he has to gain from carefully studying carburetion, electric lighting, or engine starting. The technique of pneumatics has been so vastly improved of recent years that it is easy to fall into the habit of comparatively neglecting it. No general rule applies equally to all sorts of vehicles, from heavy, high powered ones to the lighter sort, unless it is such an obvious thing as that it is foolish to run on slack tires, to neglect ugly cuts, to leave nails or horseshoes stuck in treads, and so forth. Provided corners are not taken too fast large section tires have many advantages over those which are now generally used.—*British Medical Journal.*

THE PHYSIOLOGY OF GASTRIC MOTILITY.

BY WILLIAM J. MALLORY, A.M., M.D.,

WASHINGTON, D. C.

INSTRUCTOR IN MEDICINE IN THE GEORGE WASHINGTON UNIVERSITY, DEPARTMENT OF MEDICINE, AND ATTENDING PHYSICIAN TO THE OUT-PATIENT DEPARTMENT OF THE UNIVERSITY HOSPITAL.

Introduction.—Clinicians recognize in the motor functions of the stomach two degrees of impairment; motor insufficiency of the first degree (Boas),[5] in which the stomach still completely empties itself but requires a longer time to do so than is normal, and motor insufficiency of the second degree, in which the stomach is no longer capable of completely emptying itself, food remains being found even twelve hours or more after eating. The latter form, motor insufficiency of the second degree, is nearly always due to mechanical obstruction and will not be considered further in this paper.

Motor insufficiency of the first degree may be said to be a condition, rather than a disease, for it often occurs as a part of universal congenital asthenia and temporarily during physical or mental fatigue. It may also be found accompanying various chronic diseases, and is sometimes combined with other functional or organic diseases of the stomach. Whether it occurs alone or in association with other pathological conditions, it is the cause of a long list of symptoms, it greatly impairs the efficiency of the patient, and often runs a very chronic course despite all treatment. Since it is essentially a disturbance of functional capacity, it would seem that if there is to be any improvement in the present methods of treatment, the therapeutic measures must represent an intelligent understanding of the altered mechanism, with the purpose of restoring normal conditions. This will be possible only when we know the physiological means by which the motor functions are normally regulated. For a better understanding of the problem, and, possibly, for the purpose of formulating some methods of treatment based upon rational physiological means, it is necessary that the physiology of the organ be carefully considered.

General Motor Activity.—As long ago as 1679 Wepfer[45] laid the foundation for our knowledge of the normal movement of the stomach when he observed peristalsis in the exposed organs of living wolves, dogs, and cats. Schwartz[41] and Haller[21] made similar observations, but no further work of note was done in this field till 1833 when Beaumont[2] recorded his accurate observations of the movements and experiments on the digestive functions of the stomach of Alexis St. Martin, which was available for these observations and experiments on account of a gastric abdominal fistula.

Beaumont's description of the motor activity of the stomach, always enlightening, have taken on additional importance and interest because similar observations made in recent years with more elaborate instruments and a more perfect technique have added to, and explained many of the facts recorded by him. He mentioned that the alternate contraction and relaxation, when affecting the transverse diameter produced vermicular or peristaltic motions while contraction of the longitudinal muscle fibers approximated the splenic and pyloric portion, and when all acted together, the cavity was reduced in size. The food on entering the stomach was noticed to pass first over the fundus from right to left, then along the greater curvature. There was no distinct line between old and new food, central or peripheral, crude or chymified, but recently swallowed food, liquid or solid, was mixed with that already partially chymified in the stomach.

Accelerated expulsion of food seemed to be effected by a peculiar action of the "transverse band" situated at the commencement of the conical-shaped part of the pylorus. On attempting to pass a thermometer through the aperture into the pyloric region during the later stages of digestion, forcible contraction was first perceived at this transverse band, and the bulb of the thermometer was stopped. In a short time there was a gentle relaxation and the bulb was passed without difficulty. It was then drawn three or four inches toward the pylorus, then released and forced back again by the stomach movements. As the bulb was drawn toward the pylorus there was felt a piston-like suction. If the bulb, when drawn to the pyloric end was detained there, or if the experiment was repeated too often, severe distress, cramp and spasm were felt, but these symptoms ceased on the withdrawal of the instrument. The normal movements of the stomach continued, however, until all food was expelled, and then the organ became quiescent. Before Beaumont's observations, the functions of the stomach were deduced theoretically from its anatomical structure. Beaumont stated observed facts, and although recent physiologists have added to the knowledge he gave us, his work still stands as a foundation for all subsequent observations.

Kussmaul in 1869[26] introduced the stomach tube and used it successfully in the treatment of gastric dilatation, but the early recognition of hydrochloric acid deficiency in advanced carcinoma led to the almost exclusive study of secretory functions, while investigation of motor functions were neglected until a comparatively recent date. For years observers had studied *in situ* the exposed active organs of living animals and also excised organs which were kept nearly normal in warm isotonic physiological solutions. Cannon,[11] however, was the first to study gastric peristalsis in animals

under practically physiological conditions. At the suggestion of Bowditch he fed cats a bismuth mixture and studied the peristaltic movements of the intestine and stomach by means of the *x*-ray. His observations were reported in 1897, and Roux and Belthazar published similar observations of a confirmatory nature in the same. Rieder appears to have been the first to study gastric peristalsis in man by this method. Later many other radiographers began to study the physiology and pathology of gastric and intestinal peristalsis, and in the spring of 1910 Roentgenocinemetographic films made by Rosenthal were shown. The radiographic examination of the stomach soon became an established clinical procedure, and the study of radiographic pictures in normal and diseased conditions of this organ has contributed very greatly to our knowledge of its motor functions. Although this is very complex and some minor details still remain unsettled, the essential features of its motility may be summarized as follows:

The empty stomach exhibits two types of rythmic movements. One is relatively feeble, but continuous, with a constant rate of contraction of twenty seconds' duration. This is always present in the empty stomach, provided the subject is healthy in every respect, but it may be obscured by the second type, which consists of powerful rythmic contractions of thirty seconds' duration.[8] If the gastric wall is tonically contracted it relaxes after an act of deglutition. Intragastric pressure, usually about 7 to 19 c.m. of water in the cardiac portion, then falls to nearly zero, and the capacity of the stomach is increased. The lowest pressure is observed apparently at the time when the bolus is delivered into the stomach by the esophagus. After about ten seconds tonus is re-established.[15]

Peristalsis of the filled stomach consists of a series of rhythmic muscular contractions originating at some point intermediate between the fundus and pylorus and progressing toward the pylorus at the rate of about one inch per second along the greater curvature. The contraction forms a slight ringlike constriction of the stomach wall, which, at first near its origin, is wide and shallow, but as it progresses toward the pylorus it becomes deeper and narrower after the manner of a wave rolling on a shallow shore, until just before reaching the pylorus, some of them form complete constrictions, entirely dividing the gastric contents. From one to four of these waves may be observed at one time, depending upon the type of stomach. In addition to these rythmic movements there is a *systole* and *diastole*, or a general contraction and relaxation, of the stomach occurring with each "gastric cycle," as the complete passage of a wave from the fundus to the pylorus is called.[13]

The pylorus does not open with the arrival of each constricting wave, but is governed by the degree of gastric acidity, stage of digestion and nature of duodenal contents. This mechanism is controlled by impulses from the cerebrospinal system reaching the stomach through the vagi and the splanchnic nerves, by local conditions if irritation in the stomach, and by reflexes from the duodenum and the small intestine. The wavelike contractions originate as a result of tension produced by internal pressure, acting on a tonically shortened gastric musculature. Both conditions must be present, because distention of an *inactive* stomach causes peristalsis when the musculature is tonically shortened, but *not* when it is relaxed, and it is noted that considerable intragastric pressure is present during peristalsis,[14] viz., from 6 to 19 c.m. of water in cardiac portion, and from 60 to 162 c.m. in the pyloric portion have been observed.[10 23]

Within certain limits peristalsis is augmented or weakened as the intragastric pressure is experimentally increased or decreased. Tension may be produced in two ways, either by stretching the tonically contracted muscle walls with increased contents, or by inducing tonus in the muscle. The shape of the stomach, conical when nearly filled, is thus seen to be a factor in originating gastric peristalsis. A definite relation must exist between the tonus of muscle and internal pressure, for the internal pressure may be too slight, *i.e.*, inadequate to induce a response in the tonically contracted muscle or it may be too great to permit contraction. This has been demonstrated experimentally by distending and partially emptying the stomach of animals under control, thus producing and arresting peristalsis at will.

Nervous Control of Movements of the Stomach.—In studying gastric motility and the means by which it may be influenced experimentally, the vagus nerves have been repeatedly investigated. Mangold[30] experimented on crows and jackdaws and found that stimulation of the peripheral end of the severed nerves, after temporary inhibition, caused acceleration of gastric movements, and increased tonus. Stimulation of the central end caused inhibition of gastric movements. Zweig,[40] after exposing the three roots of the vagus in guinea pigs, stimulated with a weak electric current each bundle separately while observing the effect on the stomach. He found that stimulation of the middle bundle always produced slow peristalsis of the pre-pyloric portion, while stimulation of the upper and lower bundles produced no effect on the stomach.

Stimulation of the upper bundle from the medulla oblongata caused contraction of the lower end of the esophagus. Cannon[12] experimented with three series of animals. One with only the splanchnics severed, a second with only the vagi severed, and a third with both splanchnics and vagi severed. He noted that splanchnic section resulted in no change of the normal movements of any part of the alimentary canal. Protein food and carbohydrate food passed through the pylorus at the normal rate, but proteid food passed through the small intestine more rapidly than usual. There was no acceleration of carbohydrate food. Vagus section resulted primarily in a tardy beginning of gastric peristalsis, marked weakness of the gastric peristaltic constrictions, retarded and slow discharge through pylorus, especially of proteids. The condition was largely recovered from in a few days. With the combined section of both vagi and splanchnics there was almost from the first normally deep constrictions. At autopsy the stomach was found firmly contracted. The characteristic rapid discharge of carbohydrate food and slow discharge of proteid food after the section of vagi or splanchnics, as well as after sections of both indicates a local control of this function. Carlson,[9] after studying carefully and thoroughly the movements of the fasting human stomach, experimented on dogs under well controlled conditions, and noted that section of the splanchnic nerves increased gastric tonus and augmented gastric hunger contractions.

Psychic or reflex influences on these movements were greatly diminished. Anger, fear, joy and pleasure no longer led to complete cessation as in

normal conditions. He thinks, therefore, it is "evident that the inhibitory fibers in the splanchnic nerves constitute the main efferent path in this type of inhibition." Section of the vagi leaves the empty stomach on the whole permanently hypotonic, for as long as three months after the operation.

With the vagi severed and the splanchnics intact, psychic or reflex inhibition was still in evidence, but not so marked. There is in this case a gradual diminution in the influence of the splanchnic nerves on the empty stomach of the dog observed for three months after section of the vagi. With section of both splanchnics and both vagi observed from thirty to sixty days later there was practically a permanent hypotonus, except in prolonged starvation. He concludes that all the essential characteristics of the empty stomach are determined by the local gastric motor mechanism, rather than by the central innervation or central inhibition. There is less change in the movements of the full stomach (in cats) than there is in the empty organ.

Since the empty stomach completely isolated from the central nervous system does exhibit the typical hunger contractions, the primary stimulus to these contractions is not to be sought in the extrinsic nerves. It seems likely, however, that under normal conditions the essential role of the vagi and the splanchnic nerves in connection with the gastric hunger contractions is that of modifying or regulating a primary autonomous mechanism in the stomach wall.

The essential findings of other experiments are in harmony with the above. Klee[25] studied vagus stimulation in decapitated spinal cats. They were kept alive for twenty-eight hours without signs of shock and with good heart action and normal reflexes. Bismuth-potato-purée was introduced into the stomach through a tube and the movements studied by the radiographic method. At first the emptying of the stomach was much retarded, incomplete, and the sphincter phylori opened irregularly. These conditions were less marked after section of both splanchnics. By faradic stimulation of the distal ends of the vagi the above impairment could be compensated or removed. Both vagi were stimulated in the neck, at regular intervals till the pulse was reduced to half its previous rate, although some marked influence was observed on stomach without any slowing of the heart. The effect was most marked on the stomach and upper part of the small intestine, less noticeable on the lower small intestine and not observable on the colon. At first there was an inhibition of all movements, then in the previously flat antrum waves appeared, strong constriction involving the whole stomach and dividing it into several segments. All these constrictions ran in peristaltic waves to the pylorus and carried the gastric contents before them. With a weak current, which did not affect the heart, the peristalsis was not so strong, but still exceeded the normal. Even after repeated stimulation a very weak current was sufficient to cause marked contractions. The bismuth purée which at first remained motionless in the fundus for three-quarters of an hour, after vagus stimulation passed promptly into the pyloric portion and with energetic movement was forced into the small intestine. There was no return of gastric contents through the esophagus. If the esophagus was empty the cardia remained closed, if it contained a bolus of food, stimulation coerced this with strong peristalsis through the cardia into the stomach.

Although the above experiments of Cannon, Carlson and others show that the stomach can still perform its function when the splanchnics are severed, we must not suppose that they are without influence when in their normal condition. Pfluger[29] showed that stimulation of the sympathetic nerves inhibited intestinal movements and his observations have been confirmed by almost every subsequent worker in this field.

Bechterew and Mislawski[3] found that on stimulation of the corpora quadrigemina, impulse passed to the stomach, some by way of the vagi and some by way of the spinal cord and sympathetic nerves, producing contractions or relaxation according to the part of the corpora quadrigemina stimulated.

Since local anemia has been observed to check gastrointestinal movements it was believed by some[31] that the inhibiting action of the sympathetic nerves was due to vasomotor fibers causing constriction of the vessels and a local anemia, but Braam. Houckgeest[7] found that when the intestines were exposed to the air until they became red by *vasomotor paralysis* stimulation of splanchnics had no effect on the blood vessels, but still inhibited intestinal movements.

Mental Influences Affecting Gastric Motility.—Cannon[13] has collected a number of experiments and observations demonstrating the important influence of emotion on the functions of the gastrointestinal tract. The effect of excessive emotion is usually more or less inhibitory, and it is significant that the signs of emotion, pallor, cold sweating, dry mouth, dilatation of the pupils, erection of the hairs, palpitation, rapid respiration, with trembling and twitching of the facial muscles, are indicative of stimulation of the sympathetic nerves, which is in harmony with purely experimental observations on the relation of the system to the functions of the stomach. He cites the case of a lady who came to Boston to consult a specialist. After spending the night at a hotel she ate the usual test breakfast and was examined an hour later at the doctor's office. There was found a total absence of hydrochloric acid and a considerable quantity of food eaten on the previous day was still present in the stomach. Inquiry of the family physician elicited the information that the patient's husband had availed himself of the opportunity afforded by a visit to the city to go on a spree. His behavior induced in her such an emotional state that the functions of digestion, both motor and secretory, were temporarily inhibited as was demonstrated later, for after a day of quiet and repose the functions were found normal. Cannon expresses the opinion that heaviness felt in the epigastrium may be due to stagnation.

Pawlow's experiments on dogs have in many instances been confirmed by observations on human beings, but variations have been noted. Hornborg[23] was unable to observe increased flow of gastric juice at the sight of food, but it is to be noted that the patient (a little boy) became vexed when food was withheld and cried, so no secretion appeared, being inhibited by the unpleasant emotions. Bogen[6] observed a child in such a passion for food that even after it was quieted and fed no secretion appeared.

Best and Cohnheim[4] found that drinking accelerated gastric motility in dogs, although the water was permitted to pass out through an esophageal fistula instead of entering the stomach. They consider this a psychic motility, analagous to the

psychic secretion observed in sham feeding. From the above observations it seems that the absence of gastric movement in states of physical exhaustion can be explained by *absence* of *vagus* impulse, and in emotional states by *presence* of *splanchnic* inhibition. Both conditions result in absence of gastric tonus, and therefore impaired peristalsis.

Influence of Internal Secretions on Gastric Motility.—The effect of the internal secretions on gastric motility does not seem to have been studied extensively, but Carlson[10] observed that parathyroid tetany in dogs does not lead to increase in tonus or contraction of the empty stomach, but to depression of tonus and weakened hunger contractions. This change is less marked in the stomach containing food.

From some clinicopathological studies[11] it appears that the adrenal secretion exerts an inhibitory influence on gastric and intestinal movements or at least interferes with impulses passing through the sympathetic, thus allowing the vagi to act unopposed.

Intravenously hypothesis extract produces powerful stimulation of intestinal peristalsis,[26] the movements being more coordinate than those produced by pilocarpias, although there is some irregularity as compared with normal movements. Its effects on the stomach have not been reported.

Influence of Foods, etc., on Gastric Motility.—There is a very definite reflex relation between the duodenal and the gastric motor functions. Joseph and Meltzer,[25] experimenting with animals by means of a small balloon in the pyloric part of the stomach and another one in the descending portion of the duodenum, found that during each contraction of the pyloric portion of the stomach, the duodenum stops its rhythmic activity and loses its tone only to resume both again as soon as the gastric movement ceases. This antagonistic action is identical to that relaxation of the esophagus and cardia during deglutition, observed by Kronecker,[29] and the relaxation of stomach during contraction of the esophagus.[15]

Cohnheim[17] considers the pyloric reflex the most important in the whole digestive tract. Normally the pyloris opens about every 15 to 20 seconds and there is a forcible expulsion of gastric contents into the duodenum. If one should inject 10 c.c. of acid gastric contents into the duodenum through a fistula, this regular movement ceases and is only resumed after from 3 to 12 minutes.

If oil is introduced instead of hydrochloric acid, the expulsions cease more slowly, and not so entirely but for a longer time.[4] A local anesthetic, such as novocain, introduced into the small intestine prevents this action. Kirschner and Mangold[27] found that complete division of the stomach from the lesser to the greater curvature produced no essential change in the functions of the pylorus and antrum pylori. The chemical reflex from the duodenum remained active, as before section.

In addition to the above duodenal reflex, the chemical composition and temperature of substances in the stomach have a very definite influence on the opening and closing of the pylorus. Isotonic solutions leave the stomach more rapidly than pure water, acid, hypo- or hyper-tonic solutions. These cause a temporary closure of the pylorus and remain longer in the stomach, becoming in the meantime, by diffusion and secretion, more nearly, but not necessarily, entirely isotonic. Hot and cold fluids remain in the stomach longer than those of 38° C. temperature. The pylorus is also closed against solids, so that only liquids, purees, and soft slippery masses pass out.

Clinical interest has induced many observers to study the effects of different foods on gastric motility. Wulach[47] found that fats, such as fat meat, cream and butter, remained in the stomach longest, while carbohydrates left the stomach most promptly. It has been observed that weak solutions (2 per cent. to 3 per cent.) of sugar leave the stomach sooner than water, while stronger solutions (10 per cent. to 20 per cent.) remain much longer, in consequence of the diffusion process.

The addition of pure albumin to water retards the emptying of the stomach, but egg albumin is less effective in this respect than other proteins, and the addition of a little sugar to an albumin solution tends to compensate this retarding influence.

Since bismuth salts are being used so extensively in radiographic work, it is proper to inquire whether such large doses do not produce some definite effect on peristaltic activity of the stomach, and so vitiate the conclusions to a certain extent. Weber and V. Bergemann[44] placed rubber balloons in the stomach and registered the intragastric pressure when the stomach contained water, bismuth carbonate, bismuth subcarbonate, milk and zirconium oxide and found it the same in each case. Recently Tabora[42] studied by means of the *x*-ray gastric peristalsis and motility in well individuals and in those having hypo- and hyper-chlorhydria. He used bismuth alone, and combined with hydrochloric acid and with oil. When hydrochloric acid was used, the peristalsis was deeper and more energetic, but the time of emptying was about 50 per cent. longer. When oil was added to the bismuth the peristaltic waves were flat and in a few minutes ceased. The time of emptying was much prolonged, although the pylorus was open. Only after several hours did peristalsis return. When 20 to 30 c.c. oil was again given, peristalsis again ceased, whether oil was given before, during, or after eating. The clinical value of this fact is very great.

Fifty cubic centimeters of a 5 per cent. solution magnesium sulphate retards the stomach movement, but accelerates peristalsis of the small intestine.[33] Intravenous or intramuscular injection of magnesium salts abolishes completely and for some time the normal peristalsis of the stomach and duodenum, as well as the contractions induced by Barium and physostigmine.[24]

Influence of Drugs on Gastric Motility.—Müller and Saxl[34] studied the effects of various drugs on the tonus and capacity of the stomach in adult healthy animals with a large gastric fistulæ. The fluid was introduced quickly (one minute) through the fistula, under a pressure of eight c.m. of water. The stomachs received under these conditions 200, 200, 210, 190 c.c. of water. The same stomach retained 400 c.c. when it was introduced through the stomach tube. When the animal was under the influence of the following conditions the contents varied, as will be seen from the results in the accompanying table:

Narcotized	700 c.c.	Atropine	290 c.c.
Under morphine	600 c.c.	Local anesthesia	230 c.c.
Chloroform internally	500 c.c.	Cocaine	280 c.c.
Chloral internally	370 c.c.	Alcohol	Variable result

Contrasted with the above there is another group which was found to increase the tonus and thereby reduce the capacity.

Physostigmine	80 c.c.	Strychnine	110 c.c.
Pilocarpine	100 c.c.	Adrenaline.	Without influence

Of mineral waters Karlsbader, Homburger, Bitter water, and Krondorfer gave a measurable increase in tonus.

The above results were believed to be due to direct action on muscle or local nerve supply, because the same results are produced in the excised perfused stomach. It is a reflex reaction, and atomy is an abnormal reduction of the stomach's resistance to filling.

Arnsperger,[1] observing the effects of morphine on the motor function of the stomach, concluded that small doses were without effect, while large doses retarded emptying by producing a cramplike action.

R. von Velden[48] examined eighty-two normal stomachs and found that morphine increased peristalsis, especially in the region of the pylorus. Tonus was increased, and while standing the stomach was incompletely distended. It emptied in the normal time, or even more quickly. If a larger dose of morphine was given, a constriction occurred in the pyloric region, which even separated the pylorus from the fundus and the picture resulted, the hour-glass stomach or an organic disease. This appeared in the lying as well as in the standing position. There was increased peristalsis and antiperistalsis. Even larger doses produced the same effects in a more marked degree. Atropine tends to counteract opium, but only imcompletely.

Effect of Surgical Operations on Gastric Motility.—The effect surgical operations may have on gastric peristalsis has been studied both experimentaly and clinically. Oseroff[37] removed part of the peritoneum and muscularis from the anterior wall of the stomach of a dog, allowing complete healing without adhesions and found only temporary retardation in the time of emptying. When he removed a larger strip 3 cm. wide, forming adhesions with the peritoneum and other organs, there followed permanent retardation both in the beginning and completion of emptying. Gray[20] studied gastric peristalsis in normal persons and after gastroenterostomy. He noted that carbohydrate food did not enter the pyloric portion of stomach for ten or twenty minutes and proteid food required thirty to forty-five minutes longer. In order to maintain or restore physiological conditions he thinks that the gastroenterostomy should be made in the pyloric part of the stomach.

The effect of gastroenterostomy and pyloroplasty on the motor functions of the stomach was studied experimentally by Cannon and Blake.[16] They used large female cats, and observed the effects of making the stoma large or small, on the anterior or posterior surface, with peristalsis waves of the stomach and intestine running in the same direction, and opposed to each other. After recovering from the operation the animals were fed a thin solution of cooked starch and bismuth, and examined by means of the *x*-ray.

These observers noted that the stomach does not act as a simple sack or reservoir for food, but the cardiac portion contracts, forcing food into the pyloric end, when it is mixed, and forced with the secretions into the duodenum. As the human stomach empties it shortens, especially along the greater curvature, and the contraction of the longitudinal and oblique lift the more dependent and movable part toward the fixed point of the cardia. It thus occurs that in the standing position the lowest part of the full stomach is some part of the greater curvature, while the lowest point of the empty stomach is the pylorus.

In one experiment when the food was seen to leave the stomach only through the pylorus, and never through the stoma, it was supposed that this orifice was closed, but when the abdomen was opened and the gut incised opposite the point of attachment, the opening into the intestine was found patent. The gut was again closed, and returned to the abdominal cavity, but still no food left by the surgical orifice. This has been repeatedly observed by others in cases when gastroenterostomy was performed for the relief of pyloric stenosis.[50]

Return of food to the stomach through the stoma was repeatedly observed without symptoms of a vicious circle. This return is most apt to occur when the stomach is distended and is due to a peculiar valorlike formation. When the stomach wall is stretched, the lips of the stoma separate, and the wall of the opposite part of the intestine is straightened and flattened against the stomach wall, forming a liplike valor which permits food to enter, but hinders its exit from the stomach. This valor formation was tested by distending the stomach with water and closing the pyloric and cardiac orifices. It was found to retain fluid in the stomach, but did not hinder a return from the intestine.

Vomiting was usually due to a kink in the intestine just beyond the stoma. This kink is an effective stoppage of contents, because, occurring just beyond the point, when the circular fibers of the gut are cut, the intestine is incapable of contracting and forcing the contents onward to straighten this kink, as it would normally do. These authors conclude from their observations that on physiological and anatomical grounds the anastomosis should be made as near the pylorus as practicable, because, although this is not the lowest portion of the stomach, when the organ is full it becomes the lowest as contraction of the muscles occurs, and the greater curvature is lifted up, and also because the pyloric portion and antrum pylori are physiologically the most active. It is here that the expulsive force is most powerful. This latter reason is especially important because intra-abdominal pressure serves largely to minimize the small factor of gravity. The peristaltic waves should run in the same direction in both stomach and intestine.

The effect of retrocolic gastroenterostomy on patents was studied in thirty-two cases by Hesse.[22] In one-fourth of the cases emptying of the stomach was accelerated. In only three cases was there insufficient action of the stoma, and in the majority of the cases the pylorus also functioned. There was no rythmic expulsion through the stoma, though the peristaltic waves remained normal. The form of the stomach was not essentially changed.

Electrical Stimulation of the Human Stomach, Effects of Gravity, etc.—Although attempted electrical stimulation of the stomach wall has been used clinically, definite demonstration of its effectiveness is lacking. Marshall,[32] working with animals, tried both the faradic and galvanic current, applied by metallic and moist sponge electrodes to the outside of the body, to the external and internal surfaces of the stomach, to the intestines, and to the rectum. but he only succeeded in producing feeble contractions at the pyloric portion, and a ring-like contraction of the intestine as if a cord were tied around it. If a strong current were used contractions of the voluntary muscles and diaphragm would occur.

This would give the patient a feeling of tension and some prominence in the epigastrium. He, therefore, thinks that electricity, as generally used, does not cause gastric or intestinal peristalsis. More recently Wiel[34] reviewed the literature which he found contradictory and experimented with faradic and galvanic (40 to 80 m.a.) electric currents directly on stomach and on the vagus. He found no alteration from the normal peristalsis revealed on the Rœntgen screen.

Ziegelroth[35] observed the effect of sleep and local cold and hot applications to the abdomen on the motor functions of the stomach and came to the conclusion that they were without influence. Ogarkow[36] after investigations carried out on himself found that gastric motility was strongest (emptying more completely in a given time) when lying on the right side or walking rapidly. Standing, sitting, lying on the left side, and slow walking were least favorable, while lying on the stomach or back were intermediate in effect.

Although the observations of Katsch[37] and Borchers refer especially to the intestinal movements, the agents which they used probably acted on all parts of the digestion tract, and are therefore of interest in this discussion of gastric motility. These authors fitted a celluloid window into the abdominal wall of rabbits and studied the intestinal movements under the influence of venous agents. Cold applied by ice, ethylchloride spray, and the ice cap at first increased tonus and produced anemia; later they exerted a quieting effect, and finally brought the intestinal movements to a standstill. When heat was applied, either with the Fohn apparatus (40° to 50° C.) or by means of a linseed poultice, it always produced an increase in all intestinal movements and an increased flow of blood. Massage induced peristalsis and hyperemia, but electricity, although applied by all the various methods, failed to produce anything that could be said to differ in character or intensity from normal peristalsis.

Drugs introduced into the blood stream, as a rule, influence the whole intestinal tract. The vagus stimulants, pilocarpine and physostigmine, produce powerful increase in motility and hyperemia (indicating that the vagus fibers go to the intestinal vessels). The movements, however, are atypical in character, and as compared with normal function, ineffectual, there being no proportion between the muscular activity and the forward propulsion of the intestinal contents. Atropine produces a quieting effect on intestinal movements, making them slower and the rythmic movements more regular. There is no vaso-constriction. Adrenalin acts suddenly, causes all motion to cease, and produces paleness. The quieting action is complete but more transitory than atropine and morphine. Psychic influences, if unpleasant, tend to inhibit movements and produce vasoconstriction; if pleasant, they are stimulative. The same investigators were able to observe the effects of some of these agents on a woman who had a large abdominal hernia, with nothing but the thin atrophic, translucent skin covering the intestines. Cold applied, either by dropping ether on the skin or by the Fohn instrument, produced an increase in tone and a cessation of movement. Heat, applied by the Fohn, was never quieting but always produced definite increase in movements.

Summary.—From the foregoing it is apparent that gastric motility is not a simple but a very complex function.

By means of the local autonomous neuromuscular mechanism the stomach is capable of performing its motor functions in an essentially normal manner, even when separated from the central and sympathetic nervous systems by section of both vagi and both splanchnic nerves.

Normally, however, the gastric motor functions are modified by many extrinsic influences. Motor impulses, and those for increasing tonus and accelerating peristalsis, pass through the vagus nerves. These impulses are increased by mental excitement and impaired by physical exhaustion.

Inhibitory influences, those for reducing tonus and retarding peristalsis, pass principally through the splanchnic nerves. These impulses are increased by mental depression and impaired by the internal secretions of the adrenals.

The functions of the pyloric sphincter are under the control of conditions in the stomach, and are modified by nervous reflexes from the duodenum and small intestine.

The following agents have a sufficiently definite effect on gastric motility to be of therapeutic value: heat and cold applied to the abdomen externally; massage of the abdomen; atropine, physostigmine, pilocarpine, either by mouth or by hypodermic injection; hypophysis extract and suprarenal extract intravenously.

Surgical operations performed on the stomach for the purpose of facilitating the discharge of gastric contents are sometimes only a partial success, or even an entire failure, when planned and executed in conformity with anatomical relations rather than physiological considerations. The size, shape, position, tonus, and capacity of the stomach vary under physiological conditions. Therefore, in a gastrointestinal anastomosis, the operation should be so performed and the stoma so situated that the discharge of gastric contents would *not* be hindered, but facilitated by the physiologic motility of the stomach. Gastric and intestinal peristaltic waves should run in the same direction. The stoma should be situated in the pyloric antrum, where the expulsion of gastric contents will depend upon peristalsis instead of gravity, and where it will be lowest when the stomach is nearly empty.

THE PRESENT STAGE IN THE TREATMENT OF SYPHILIS.

BY CHARLES MALLORY WILLIAMS, M.D.,

NEW YORK.

THE old doctrine that the treatment of syphilis should not be begun until the diagnosis is firmly established, while still held by a large proportion of the authorities on the subject, is losing much of its force, in view of the advance in knowledge in the past few years. We no longer wait for the appearance of the secondary eruption on the skin or mucous membranes, as the *Spirochæta pallida* may usually be discovered easily in the secretions from the chancer; and its presence is pathognomonic. But there are still some early cases in which we are in doubt: the history of the development of a lesion at a reasonable interval after exposure and the clinical picture may be suspicious, while the microscopical findings are doubtful; at so early a period the Wassermann reaction is usually negative. Under these circumstances, is it better to wait till the organisms are discovered, as Hoffmann[1] advises, or to begin treatment at once, as Neisser[2] recommends? The latter appears to be the wiser course. Hitherto it has been customary to wait for a positive diagnosis in order that we might

have sufficient grounds to insist upon the prolonged treatment, lasting at least two or three years, by which alone we might even hope to eradicate the disease. Without such positive knowledge the patient was only too sure to cease treatment as soon as his fears were allayed. Now, by a series of Wassermann tests, especially if a provocative injection of salvarsan is given, it is possible to arrive at a reasonable assurance that the disease is extinguished, even within the first year, if indeed our therapy has been so fortunate. Even the few days saved by beginning treatment at once, rather than waiting till the spirochete are discovered, in case the first search is fruitless, may be of vital importance, for we realize now as never before how early the invading organisms may reach the central nervous system, and how difficult the attack upon them becomes, once they have advanced so far. It is the permanent and progressive injury to the nervous and the vascular systems that make the disease the scourge it is in its later stages, and both are often attacked from the earliest period. To prevent the injury of these vital systems, it is important to begin treatment at the earliest possible moment, and to rid the body of its invader in the shortest possible time.

Until the past few years, the best hope was in the energetic use of mercury. Then came Ehrlich's brilliant discovery, and for a few weeks there was hope that a single injection of salvarsan would work a cure. That dream is past, and now we know that not one nor five injections of salvarsan alone will in the majority of cases be sufficient. It is no longer necessary to use salvarsan alone on the plea that only by so doing can we test its efficacy. Its efficacy is already tested; it works wonders, clinically, lesions long resistant to mercury disappearing under its use as snow before the sun, but only after repeated use, and not always then, can we expect the Wassermann reaction to become and to remain negative, and so long as the Wassermann reaction is positive we cannot claim a cure. The results of the use of mercury and salvarsan together are better, and up to the present time this is the best method known.

If the case be still in the primary stage, it may be well to excise the chancre, if this may be done without producing deformity, as when the sore is situated on a loose prepuce, because by so doing a certain number of spirochætæ are removed at once; but after all the real benefits of this operation are problematical, the important part of the treatment is the constitutional.

The way in which mercury is given is very important. Injection is probably the best method, though inunction is very efficacious also; the choice will be determined largely by circumstances such as the necessity for absolute secrecy, the possibility of having the rubbing intelligently performed, the patient's endurance of pain. Administration by the mouth has no place here; it may be useful later in the disease, but not in the early stages, where the object of treatment is to secure the maximum effect in the shortest possible time. It is best to begin with an intramuscular injection, say of one grain of the salicylate of mercury in liquid albolene, and to follow this in a day or two with an intravenous injection of salvarsan or of neosalvarsan, 0.2 g. or 0.3 g. respectively for a man, 0.15 g. or 0.2 g. for a woman. The object in giving the mercury first is to prevent the reaction which is so common after the first injection of salvarsan, and which is probably due to endotoxins arising from spirochætæ killed by that drug. The action of mercury is much slower, and apparently gives the system time to destroy these poisons without any appreciable reaction. The object in making the first dose of salvarsan so small is to test the reaction of the patient, and so to avoid the danger of injury to the nervous system by the drug itself. If these initial doses are well borne, as will be the case with practically all patients, both drugs should be given again in four or five days, the salvarsan this time in larger dosage, say 0.3 g. for a man; and then salvarsan is to be given at ten-day intervals, in doses of 0.4-0.6 g. each, for four more injections. The mercury, meantime, is to be continued in full doses, by injection or inunction. The patient should be warned to take a mild cathartic the night before the injection of salvarsan, to eat very sparingly that day, and to keep quiet for about eighteen hours after. With those precautions ambulatory treatment is safe, and is now the rule rather than the exception. Such a course will frequently prevent the development of a Wassermann reaction in primary syphilis, or convert an early positive reaction into a negative one. It should in any case be followed by a period of rest from all specific treatment lasting four to six weeks, during which the patient's general condition should receive careful attention. The Wassermann reaction should be tested at the end of this time and if found to be positive the whole course should be repeated; if negative, the second course may be made considerably shorter, but both mercury and salvarsan should still be used. The subsequent treatment will depend on the results of the Wassermann tests, and on the occurrence or non-occurrence of clinical symptoms. So long as there are any signs of the disease, whether clinical or shown by laboratory findings, treatment by courses of mercury and salvarsan should be continued and no patient should be considered cured until he has shown a negative Wassermann reaction for at least a year after the last course of treatment, and after a provocative injection of salvarsan.

This plan is of course a mere outline and details will vary with the physical condition of the patient, the character of his lesions, and his response to treatment. Either salvarsan or neosalvarsan may be used; the former is, apparently, a little the more powerful, but the technique of its preparation is more complicated, it is more irritating to the vein, and any leakage into the surrounding tissues is much more serious. (The intravenous method of injection is now used almost exclusively.) Neosalvarsan has also the great advantage that it can be given in concentrated solution, 0.9 g. in 20 c.c. of distilled water[3], thus simplifying the apparatus necessary, and reducing enormously the danger of using water not absolutely freshly distilled.

When salvarsan was first used, there were many reports of severe affections of the cranial nerves, often with severe headache and fever. These symptoms were, by many, thought to be due to the action of salvarsan itself on the nerve tissues. They seldom or never occur when treatment is begun with small doses, especially when accompanied or preceded by mercury, and what is even more significant, the symptoms yield to further treatment with mercury and salvarsan; these are due to the disease process itself, aggravated by the setting free of toxins by the destruction of the spirochætæ. Their great importance lies in the fact that they show

that the nervous system is already involved, and they demand, therefore, the most thorough and painstaking treatment. The doses, however, should be small, as large doses are apt to aggravate the symptoms, at least for a time. It is in these cases, in the early stages of the disease, that lumbar puncture and the examination of the spinal fluid are of such great diagnostic value, and it is probable also that they would be greatly benefited by the intraspinous injection of salvarsanized serum.[4]

Paresis and locomotor ataxia are now proved to be manifestations of syphilis, but treatment by ordinary methods has been unavailing. Large doses of salvarsan, intravenously, combined with mercury or not, have only a slight and temporary effect on the course of these diseases, and on the pathological changes in the spinal fluid which accompany them. It was to meet this condition that Swift and Ellis evolved the treatment by the intraspinous injection of salvarsanized serum which is at present the most promising method we have.

Potassium iodide still has its place in the treatment of syphilis, especially in the latter stages. Its use is now advised also in the earlier stages, with the object of increasing elimination, and of making the spirochætæ more accessible to the active parasiticide drugs. For the same purpose, recourse may be had to balneotherapy, massage, and any measure which tends to increase the elimination and to improve the circulation; but it is doubtful how much is really gained by these methods. It is now easy, ordinarily, to remove rapidly the clinical symptoms of syphilis, but to assure a permanently negative Wassermann reaction, to destroy the hidden and perhaps encapsulated colonies of the organism, this is, in many cases, difficult. Our treatment is not yet ideal; it may well be that some cases will react better to hectine or some of the other organic compounds of arsenic; and the laboratories may yet provide us with more valuable drugs.

Salvarsan is a powerful drug, and it should be used with caution especially in diseases of the kidneys, the central nervous system, and the smaller blood-vessels; but with careful technique and the use of small doses at the start, and with sufficient intervals between the doses, the number of accidents is growing progressively less.

To sum up: Every case of syphilis, and especially in the early stages when the chance of complete recovery is best, should be treated with both salvarsan and mercury, unless there is some special contraindication to one drug or the other, and treatment should be continued in courses of four to seven weeks, with intervals about six weeks, until all symptoms have disappeared and the Wassermann reaction is negative.

The Metabolism of Atrophic Infants.—A. Niemann concludes from his study of two atrophic infants that the carbon-dioxide excretion estimated with reference to the extent of the bodily surface is precisely the same in marantic as it is in normal infants.—*Zeitschrift für Kinderheilkunde.*

REPORT OF A CASE OF TUBERCULOSIS OF THE SCLERA OF PROBABLE PRIMARY ORIGIN.*

By GEORGE HUSTON BELL, M.D.,
NEW YORK.

The great achievement of Robert Koch has supplied us with a means by which we can learn through a specific reaction if active or latent tuberculosis is present in the human body. Tuberculosis of the sclera will always be of interest to the ophthalmologist whether primary or secondary on account of the rarity of the disease and as Verhoeff has pointed out it is a commonly unrecognized form of tuberculosis. The case which I wish to report has some unusual features and I thought it might be of interest to the society.

Miss A., white, aged 20, was referred to me June 1, 1913, by Dr. H. D. Long of New York for the treatment of the eye condition. Patient gave an indefinite history of having injured the eye as she thought while dressing her hair. She consulted her family physician, Dr. Long. He prescribed some yellow oxide ointment. After this the inflammation did not subside, but she continued under his care and treatment for one month before she consulted me. The eye gradually grew more painful and the inflamed zone so increased and was complicated by the development of hard reddish nodules in the sclera that he thought it best to consult an oculist. Tuberculin had already cleared up the diagnosis for him. On examination I found two or three definite nodules in the sclera, on the temporal side, about 3 m.m. from the limbus. The injected conjunctiva could not be moved over it. The nodules then appeared dark red or violet in color. Another larger dose of tuberculin was given to further confirm the diagnosis. At this time .00004 gm. of tuberculin bacillen emulsion ("B. E.") produced the following reaction: marked infiltration and erythema at the site of the injection, marked constitutional symptoms. Her temperature rose to 101°, and she complained of great headache. The focal reaction in the eye was most pronounced, increased chemosis, and congestion of the conjunctiva and sclera. The eye was excruciatingly painful, but unattended by any secretion save excessive lachrymation. At this time there was no iritis, cyclitis, or keratitis. I advised weak solution of atropine and hot applications in addition to the tuberculin.

Vision:
O. D. 20/15 with correction.
O. S. 20/30 with correction.

On June 5 I saw her again, after she had had another dose of tuberculin. The eye was somewhat more injected. The conjunctiva could not be pinched up from the solid mass which remained in close apposition with the subjacent sclerotic. I found we had here to deal with a diffuse deep scleritis. The treatment was continued.

On June 10 the inflammation in the sclera seemed to be extending and the nodules were more painful. The tuberculin injections were kept up by Dr. Long. I did not see the patient again until June 20, at which time the swelling had increased. The mass was extending both toward the periphery and the limbus, and the inflammation had extended to the cornea and ureal tract. The nodules were dull reddish in appearance. The veins were thickened and the blood darkened, giving the veins a paralyzed look. The pupil was contracted. The strength of the atropine was increased and the hot applications continued, in addition to the tuberculin injections.

On July 1 I next saw her, when she was more comfortable. Up to this time she had had twelve injections of tuberculin. The process did not seem so angry. There was less congestion and the nodules were not so swollen, but there was an infiltration of the cornea at several spots. I did not see the patient again until July 16, at which time the first drawing was made by Dr. Percy Friedenberg. In a letter to me he described what he saw as follows: "On the temporal side of the cornea about at the horizontal meridian there is a de-

*Read at the annual meeting of the American Ophthalmological Society at Hot Springs, Va., May 12, 1914.

cided crescentic opacity near the limbus, and at the limbus a small, flat smooth nodule of chamois leather, or pinkish buff color. Continuous with this, and spreading through the sclera to the outer canthus, there is an area of inflammatory thickening and injection. General color, dull pink or old rose, not uniform, and near the upper margin of the area, which is broadly ribbon shaped, there runs an enlarged vein of dark rose color. The scleral infiltration is soft in appearance, almost jelly like; the corneal nodules more consistent. There is very little general conjunctival injection."

I did not see the patient again for about one month. She went away to the country, but kept up the injections of tuberculin and eye treatment.

On August 16 the thickening of the cornea was softer looking and more greyish and the congestion of the diseased sclera not so pronounced. The dose of tuberculin was rapidly but cautiously increased. Patient was now getting .0001 gm. of tuberculin every four days.

On September 1 the patient's eye was not so well. There was increased capillary pressure and venous engorgement, and, locally, circulatory disturbances which led to increased transudation and swelling of the nodules. The cornea became involved by interstitial infiltration, which was localized in the form of round placques near the margin of the limbus. The treatment was continued.

On September 15 I next saw the patient. The condition seemed to be slowly subsiding, but there was still slight iridocyclitis, due to the inflammatory process having extended from the sclera to the ciliary body.

On September 24 the patient was given .02 gm. of B. E. and on September 28 she was given .04 gm. On October 2 she was given .06 gm. and on Ortober 6 the dose was cut down to .01 gm. on account of general reaction. The injections were continued every four days.

On October 19 the patient showed the encroachment of scar on outer border of the cornea and a further encroachment below on temporal side. There was a decided injection of sclera over the affected area, purplish in color, and marked injection of vessel leading to outer canthus. She was given .028 gm., with severe general reaction, marked reaction of lesion, and marked infiltration and erythema at the site of injection. The injections were discontinued.

On October 29 the eye was much better. The infiltration in the sclera was absorbing, leaving behind a slate colored cicatrix. The pupil was dilated and the eye was not sore or painful. This peculiar slate colored pigmentation not only points to the diagnosis, but gives the etiology as well. Dr. Friedenberg made his second drawing. You can see the patch of scleral discoloration, also the remains of the dilated and tortuous vein.

On November 7 the patient was given .00002 gm. and the dose was gradually increased again until she had her last injection on December 5, which was .0004 gm., when the eye had apparently recovered and was perfectly quiet and the treatment was discontinued. The eye has remained quiet up to the present time, February 15, 1914. Her vision now is

O. D. 20/15 with + .50 axis 105°.
O. S. 20/20 with — .50 + 1.50 axis 90°.

Except for the scars on the cornea and the pigmentation of the sclera, you would not know that anything had ever happened to this eye.

Prior to sending her to me Dr. Long had made a thorough physical examination of her lungs, which was negative. Patient well nourished and healthy. Also there was no enlarged or diseased tonsils and no bacilli could be found in the sputum. Family history good. We did not subject this lady to the Wassermann, as we did not think it was necessary. Verhoeff[1] claims that these nodules in scleritis with the reaction are conclusive evidence of the tuberculous nature of the process. The question naturally arises, how was the sclera infected? Was it primary?

Some ophthalmologists claim that deep scleritis is always secondary. Parsons[2] is in doubt on the subject. A close observer like Weeks[3] calls attention to two cases of apparent primary tuberculosis of the sclera. One of the cases was reported by Brailey[4] of a young girl who was treated at Guy's Hospital. The other was Müller's[5] case which was a cyst of sclerotic, the walls of which were composed of miliary tubercles. Goerdeler[6] in his exhaustive article on rare forms of tuberculosis reports six cases of primary intestinal tuberculosis, one primary of the uterus, one primary of the liver and three primary cases of the urogenital, no other lesion being discovered at necropsy.

We all know that it is possible to have a primary tuberculosis of the conjunctiva following an injury. The history of traumatism followed by prolonged inflammation and infiltration together with the absence of any signs of systemic involvement, leads me to believe that the sclera was inoculated by the lodgement of dry bacilli in the form of dust on the conjunctiva, through which the germs passed at the time of the injury.

Notwithstanding all our advanced methods of examintion and points in differential diagnosis, we cannot state as an absolute fact that any case of tuberculosis of the sclera is primary, but the preponderance of evidence in this case indicates that it was primary. It is interesting to note that this patient had fifty injections of tuberculin. The last dose was given on December 5, at which time 0.0004 gm. was given. Fifty injections seems like a small amount to give a patient when we stop to consider that White[7] of London has taken over 500 doses himself, extending over a period of seven years, for general tuberculosis. White has now watched many patients who have taken tuberculin steadily for periods varying from two to five years. Cases of tuberculosis of the eye, of bones, of glands, of the skin, and of the throat, and the improvement in many of the cases was due to tuberculin and to tuberculin mainly.

Fenwick[8] speaks of two ways of giving tuberculin, one by hypodermic injection and the other way by the mouth. The former is obviously the more scientific and the latter has been generally condemned as of no value. Nevertheless, it is a method that Fenwick has employed as a routine in the out-patient department and he speaks of it in the highest terms.

In concluding, will say that from the experience I have had in treating scleritis, sclerosing keratitis, and anterior uveitis with tuberculin, I have found that it is not necessary to increase the dose of tuberculin to farthest limit of tolerance. I believe strongly in small doses to begin with, gradually increased and continued over a long period of time. I have never seen any harm result from its use. Well-diluted tuberculin treatment constitutes a real and great therapeutic progress.

THE NEGLECT OF THE AGED.

By I. L. NASCHER, M.D.,
NEW YORK.

It needed the pen of a Dickens to rouse the public conscience to the neglect of the dependent child. In Oliver Twist, the child of the workhouse, he planted the germ of discontent with existing conditions, and this germ grew and multiplied and spread until the child today has the world for its guardian.

Could some kind Dickens of our time with equally persuasive and forceful pen study and expose the conditions in our almshouses and asylums for the aged he might with equal success rouse the public conscience to the neglect of the aged. And as interest in the dependent child led to the scientific study of child welfare, so might an interest in the dependent aged lead to the scientific study of senility, of the needs and wants, the peculiarities and infirmities, the happiness and welfare of the aged. There is not, so far as I know, any organization taking up the scientific study of the aged, not a journal devoted to their welfare, no movement of any kind interested in their betterment. International congresses are held to discuss child conservation, while the aged receive but the scantiest attention. The aged in institutions are dealt with as they have been dealt with for generations, though here and there some official who possessed the initiative and determination, coupled with sympathy and common sense, has introduced innovations that tended to make his aged charges healthier and happier.

The medical care of the aged has received but little consideration; indeed, it is only a few months ago that the first modern American work on this subject appeared.*

It is hardly necessary to discuss the causes for this neglect. I have referred to this matter repeatedly. There are few so altruistic that they can completely eliminate thoughts of economic value from their humanitarian spirit. In a former paper on this subject I said: "In this utilitarian age we gage the desirability of men and things by their practical value," and this applies as well in the work of philanthropy as in other fields of human endeavor. It applies with special force to the medical profession who have heretofore neglected the aged, using the term "old age" as a handy excuse for a diagnosis and a cloak for ignorance. We are only beginning to realize that old age is not a disease any more than childhood is a disease—that it is a period of life in which certain diseases prevail, while other diseases prevalent in earlier life do not occur; that the aged present many interesting medical problems; that they require special study and special care.

But the altruism of the physician is tinged with the spirit of commercialism, and it is influenced, consciously or subconsciously by the factor of economic value. The child has a prospective economic value, the patient in the hospital may if he recovers have an economic value; the aged are nearly, if not quite, economically worthless.

In many cases the sense of uselessness is imposed upon the aged by those who do not know the mental and physical capacity of the aged individual. In a mistaken spirit of kindness the aged person is withdrawn from his accustomed routine of life and is made to feel that his usefulness to mankind is lessened, and if he is at all sensitive he realizes that he is no longer a producer, but a consumer, and a burden. Not only in this, but in many other directions does the ignorance of senile mentality and the senile organism tend to the detriment of the aged, making them more unhappy, increasing their infirmities and shortening their lives. I have visited a number of institutions for the aged and found in every one, even in the best and most elaborately equipped, this lack of knowledge of the senile mind and body leading to faults in the care of the aged which could be avoided.

Much can be said in favor of institutional care of the aged; more can be said against it. Where expense is the deciding factor the rending of home ties, the separation from the family and friends, the changing of lifelong habits, the loss of self-respect in the recognition that one is virtually a pauper dependent upon the bounty of the community or body maintaining the asylum, the inevitable mental depression that follows inactivity with gloomy retrospection and dismal foreboding, all these count for nothing against the lower cost of maintenance in the institution.

Dr. Paul Ritter, Minister of Switzerland, informs me that in several cantons—Zurich, Thürgau, Appenzell, Uri, Basel-land and Lucerne—the poor and aged are cared for in asylums and in private families. Some place the dependents in different families alternately, while Zurich places its dependents with private families only in the country districts. He says this system has certain drawbacks and has not proved to be very satisfactory. From a purely humanitarian standpoint the family care of the aged is incomparably better than institutional care. The child brought up in an institution is accustomed to institutional life. The aged find in institutional life a constant, galling restraint, a severance of their past freedom; family relations and ties are disrupted; domesticity, privacy, independence, the love of home, even interest in life are lessened, suppressed or entirely abolished. Life becomes one dreary, monotonous routine, the mind becomes apathetic, the body becomes weak, existence becomes automatic; a helpless, hopeless, purposeless existence dragging along to its dismal end. How different in lands where reverence is done to the aged, where sympathy is not measured by cost, where old age pensions enable the aged to maintain their little homes or aid the family to support them, and not force them to the dreary, soul-destroying life of the poorhouse.

It is not my purpose here to appeal to the heart (though I hope this may touch the conscience), but to show faults in the care of the aged in some institutions that I visited, and how some of the faults may be remedied with little or no expense. We must remember that the asylum is usually the last resort, that the inmates enter when they can no longer earn a livelihood, when they have no means or family ties or when the family cannot or will not look after them. The separation from home, family and friends is itself depressing, and this depression is increased by the sense of lost independence, in enforced obedience to rules which ignore personal wishes and lifelong habits, and the sense of dependence upon public or private bounty. Other depressing influences are the unavoidable association with undesirable companions in misery, the segregation of the sexes and lack of mental occupation, permitting the mind to look back with regret or forward in despair.

*Nascher: Geriatrics. The Diseases of Old Age and Their Treatment. Philadelphia, 1914. P. Blakiston's, Son & Co.

I know of no more senseless, heartless rule than the segregation of the sexes. In the few institutions in which the men and women are permitted to associate they take better care of their personal appearance and they take an interest in life. The effect of segregation as compared with free association of the sexes is clearly observable in the New York City Farm Colony. Married couples are housed in cottages, where each couple occupies a separate room. The inmates meet each other, take an interest in each other's welfare; they take a pride in their personal appearance and in the appearance of the cottage and their rooms. In other parts of the institution the sexes are segregated, the inmates become indifferent to their appearance, slouching in their attitude, apathetic or morose. The superintendent occasionally secures the services of an orchestra or a dramatic company which give a concert or performance in the open, the inmates sitting on a terrace which they constructed for this purpose. On these occasions the men and women sit together and both men and women fix up to look neat and clean.

In the Home of the Actors' Fund, which is conducted like a good family hotel, the inmates are called permanent guests and they associate as freely as they would at any other hotel. They take pride in their appearance and in the appearance of their Home and of their rooms, some of which are elaborately decorated by the inmates occupying them. The inmates belong to the theatrical profession, and, being accustomed to hotel life, find here as close a semblance to their home life as is possible in an institution, with the advantage of a beautiful situation and beautiful grounds, marred only by the proximity of an adjoining cemetery, a constant reminder of death. The dining room has small tables seating four to six guests. Aside from the necessary restrictions as to rising, meal and closing hours, the inmates are free to come and go at will. They have a well-stocked library, smoking room, billiard room, parlor, sewing room, etc. This institution, now holding thirty-five guests, and which can hold one hundred, is the model institution of its kind. The principal fault here is lack of occupation for the men, for, while they are not accustomed to manual labor, the routine becomes monotonous and they become apathetic. Being considered guests, they are not urged to do anything, and they lead lazy, purposeless lives, and mind and body become "stale" from inactivity. There is no infirmary ward, and an inmate becoming ill remains in his room while a neighboring physician is called in. If the illness is serious the patient is removed to a hospital several miles away. The superintendent is a graduate pharmacist, well able to take care of minor ailments and to give emergency relief.

While most of the aged in institutions are more or less ailing or complaining, few institutions have a resident physician. In the New York City Farm Colony, with 1,000 inmates, nearly 100 were in the hospital wards, in charge of a single nurse and one visiting physician. There is nearby the Sea View Hospital for Tuberculosis, from which a physician could be summoned in an emergency, but the interne of a tuberculosis hospital is as little prepared to treat senile cases as the ophthalmologist would be to perform a cesarean section. With a growing interest in geriatrics in medical schools, it should not be difficult to secure internes for homes for the aged. Surely the aged invalid, who has sense and sensibilities, who feels the physical pain of disease and the mental anguish of neglect, who has been of some service to mankind while he was able to be of service, deserves at least the attention that is given to the idiot and imbecile, who have a resident physician in their institution.

The National Home for Disabled Volunteer Soldiers and the various state homes for soldiers and sailors generally make suitable provision for the ill and ailing. Let me quote here an extract from a letter from Dr. James E. Miller, Inspector General and Chief Surgeon of the National Home for Disabled Volunteer Soldiers:

"There are ten branches of the National Home for Disabled Volunteer Soldiers. Each branch has a hospital with bed capacity sufficient to care for one-fourth of the members present; comfortably furnished, amply equipped with modern instruments, appliances and apparatus necessary for the proper care of the sick. At four branches there are special facilities for treatment of tuberculous patients. The hospitals of the Home are equal in points of efficiency and equipment to the best in the country. There are sixty-five efficient surgeons on the medical staff of the Home."

I have not visited any of these homes, and base conclusions solely upon the published reports. The inmates are well supplied with amusements and recreations, but not with occupations which would keep their minds occupied. This probably accounts for the large number of cases of drunkenness reported. At one branch 680 out of 968 minor offenses were drunkenness out of an average number present and absent of 2,626 (1913 report). The food is plentiful, but some articles are clearly unsuitable for aged ailing individuals.

The City Farm Colony is a branch of the New York City Homes for the Aged and Infirm, the institutions formerly called the Almshouse and the Poorhouse. Of its 1,000 inmates about 100 were in the hospital building and nearly 700 were employed in the fields and shops and on construction work. This institution can serve as the model for the systematic employment of aged dependents. The inmates are mostly from the lowest and poorest stratum of society, many are ailing, others complaining, others lazy, but the able superintendent has succeeded in instilling in his charges a sense of usefulness, and they work cheerfully, many without supervision. They are urged but not forced to work, they are not hurried, and they rest when tired. The men work at trades with which they are familiar, those having no trade working in the fields, on construction work or in the broom factory or other shop where skilled labor is not required, working eight hours a day. Those least able to work set and clear away the dishes on the tables in the dining hall, while a few of the more able-bodied and better-educated men are made overseers at nominal wages. The women look after their dormitories, sewing and laundry.

The work is so thoroughly systematized that there is employment for all, nearly everything about the institution, on the fields and in the shops is done by inmates, and the products of the fields and shops are disposed of, so that the cost of maintenance is reduced to about 31 cents a day per inmate, said to be the lowest cost per inmate in any public institution for adults. The great advantage is, however, that the inmates have their minds occupied with their tasks, they feel that they are not entirely useless and their thoughts are not fixed on self and death.

This institution is conducted along strict institutional lines, with rigid rules, clearly defined duties and absolute restrictions. These rules and restrictions are probably necessary to control so large a body of paupers who are unaccustomed to cleanliness and order, yet much could be done to make their lives brighter and make them more comfortable without impairing discipline. In all my writings I have urged mental stimulation as the most effective means of warding off the mental depression which leads to melancholia and dementia. The frightfully monotonous life in the institution leads to a lethargy in which the individual becomes an automaton, acting mechanically through force of habit. It is a simple matter to stimulate interest in life while the individual still has some interest; it is difficult to rouse him out of his lethargy when he has once reached that condition. One of the most potent measures to keep up interest in life is through newspapers and the discussion of the affairs of the day. Newspapers and other reading matter could probably be obtained at little or no expense, but the aged generally have presbyopia, and they cannot read without proper glasses. The mental impression produced when we read a paper is much more powerful and lasting than when we hear it read. If these poor people were supplied with glasses and newspapers they would take a greater interest in life and in themselves. Here is a fruitful field for public and private philanthropy. I was informed that no provision was made for recreation or amusement, that the superintendent upon his own initiative secured the orchestras and dramatic talent which gave the occasional performances to the inmates. On rainy days, when the inmates cannot go to the shops or work in the fields they remain indoors and do nothing—nothing but think with regret of the past, in despair of the future. There is no piano or phonograph to chase sad thoughts away, no games like checkers or chess to while away dreary hours. True, they are paupers, they may have been improvident; now they are unfortunates and look for sympathy and kindness.

In one institution near Vienna there are enough inmates able to play musical instruments to form a good-sized band, and they give occasional public concerts. The income from these concerts supplies the inmates with little luxuries which they procure at a canteen on the grounds. It would probably not be possible to recruit an orchestra from the inmates of the Farm Colony, but out of a thousand inmates one or several would be found who could play the piano.

A universal fault in institutions for the aged is improper feeding. The falling out of the teeth is nature's signal that food which must be masticated is to be avoided. The principal article of diet which requires chewing is meat. Almost all other foods can be crushed between the tongue and hard palate, either dry or when moistened or soaked. Fats and insipid articles of food are distasteful and they should be avoided on physiological grounds. While it is not practicable in a large institution to furnish meals suitable to each individual, it is possible to so arrange the dietary that those unable to chew can get sufficient food without meat. In the New York City Home a pious Jew would not eat proscribed dishes and almost starved until he was transferred to a Jewish home for the aged. In one institution the superintendent introduced a cathartic in the food one day each week, a pernicious practice, heartless as well as ignorant. Drugs should never be given indiscriminately, never without a physician's order, or so as to incommode other inmates.

A fault which prevails in many institutions is inadequate bathing facilities. The aged find it difficult to enter a bath tub and more difficult to get up after the bath. Stout women are often unable to get up without assistance, and for this reason they dread the bath tub. This trouble can be avoided by using a shower bath and allowing the bather to sit upon a chair.

In one institution there were no carpets on the floor, the inmates were not permitted to go barefoot, but several had bladder and prostatic troubles which compelled them to go to the toilet at night. When this happened they awoke the whole dormitory. A strip of carpet removed this source of insomnia. In another institution the windows were opened during the day even in winter. At night they were closed and the heat was turned on. The bedding during the day was folded over the foot of the bed and the bed was still cold when the inmates retired. They could not fall asleep until the heat from their bodies warmed the bed sufficiently to make them comfortable, and those who had bronchitis began coughing as soon as they entered the cold bed. As there were a lot of empty mineral water jugs in the cellar, I suggested that the inmates fill these with hot water and each one put a jug in his bed as soon as he went to the dormitory after supper, and when he entered the bed he could push the hot jug to the foot of the bed and keep his feet warm.

Many aged persons have bromidrosis, and where a large number congregate in a room the odor soon becomes exceedingly offensive. In one institution there is no infirmary ward, and there are several bedridden cases in the dormitories. During a cold spell the windows could not be opened for a few days, as the bedridden patients could not be shifted and the atmosphere became nauseating. In one institution the inmates are paired off so that each one has a companion. The companion of an inmate who had hemiplegia acquired through mimicry a similar gait, and in another case an inmate acquired a senile tremor in like manner. Separation and disciplinary measures were necessary before it was possible to overcome these habits. In another case association with a garrulous dement resulted in a quarrel in which the dement was injured and the other developed delusions of persecution.

Other faults frequently met with in institutions are neglect of the petty ailments, such as broken down arches, corns and bunions, pruritus, pains in the joints (arthrosclerosis), etc.; lack of canes, the presence of curiosity seekers and professional sympathizers, inadequate facilities for holding religious services, mingling of nervous and mental defectives with impressionable, healthy cases, irrational amusements and recreations, uniform costumes, sometimes lack of sympathy and interest on the part of the superintendent in his charges, more often failure to encourage interest of the inmates in their institution.

Not alone should the inmates of asylums for the aged be urged to keep their minds and bodies employed, they should be permitted to dispose of their products or abilities and use their earnings for the general betterment of their institution. The object should always be to instil a sense of usefulness, even if it be only the ability to go on errands.

Segregation of the sexes should be prohibited, and as the association of the sexes will rouse pride in appearance they should have the facilities to

enable them to make a good appearance. This is not so important in soldiers' and sailors' homes, but in other homes this separation from the opposite sex is a hardship for which no good reason can be given. Such association will arouse interest in others and in the surroundings. A distinctive pauper costume is as humiliating as are the prison stripes.

In the course of this paper I have touched upon some other factors applicable to the institutional and communal care of the aged which should receive careful study. Such are the cottage system of housing, the distribution of aged dependents among families, the earning capacity as a contribution to the cost of maintenance, systematic employment, the canteen, stimulation of interest in the institution and in self, etc. The City Farm Colony has a well-equipped printing office manned by inmates, which could publish a weekly or monthly journal dealing with the institution and department and to which inmates could contribute.

These matters deserve attention and study, far more study than one individual working without assistance can possibly give to them. But to receive attention it will require the forceful and persuasive pen of a Dickens to rouse the public conscience to the neglect of the aged.

631 East One Hundred and Sixty-eighth Street.

A MEDICAL BUGBEAR: DISPENSARY ABUSE.

By MICHAEL M. DAVIS, JR., Ph.D.,

BOSTON, MASS.

DIRECTOR OF THE BOSTON DISPENSARY.

About three million men, women, and children are now receiving treatment annually at the seven hundred odd dispensaries and out-patients departments scattered over thirty-eight of the forty-eight States of the Union. What is the greatest problem of these seven hundred institutions? On first thought it would seem to be: to give efficient treatment to their three million patients. But no! If we may judge by the most prevalent topic of discussion, the prime dispensary problem is to keep persons from getting treatment! Those persons, to wit, who are not "proper objects of medical charity" because they can pay. "Dispensary abuse" (by "persons able to afford private physicians") has been talked about in this country for twenty-five years. The subject of dispensary efficiency is but just beginning to be broached.

To exclude an improper clientèle is no doubt a fair requirement of an institution (if we can decide what "improper" is to mean). But to give efficient service to its proper clientèle is the first duty of an institution, if it is to exist at all. Efficient medical service to three million persons in the United States is a public health matter of considerable magnitude; and it is unfortunate that discussions about dispensary "abuse" have thus far crowded out almost all discussion of efficiency. Since it is happily true that the emphasis now appears about to shift, as it ought, it seems timely to review what has been said about this bugbear of "abuse" and see what is has amounted to.

Three dispensaries were founded in the United States in the eighteenth entury, but the number increased very slowly until toward the close of the nineteenth. Discussions of dispensary abuse began to appear in our medical journals after the year 1875, and became frequent after 1890. In New York City, where dispensaries multiplied earlier than elsewhere, the problem naturally came earlier to the attention of the profession, and provoked varying comments. "A Propagator of Pauperism: the Dispensary" was the title of an article by Dr. George F. Shrady, published in 1897 in *The Forum*.[1] "It may be broadly stated," says the article, "as the result of exhaustive statistical study, that fully 50 per cent. of the patients who apply for free medical aid are totally undeserving of such charity. . . . In New York City alone there are 116 dispensaries, each of which is vying with the others in propagating the worst form of pauperism."

As an example of another view, from a widely different standpoint, we may quote from a paper by Dr. W. S. Thayer[2] in which he cites, with general approval, an "eminent physician," unnamed, as follows: "My views on dispensary abuse have never been winnowed and tried out by careful investigation of the subject, but so far I think the chief dispensary abuses are: (1) The abuse of patients by careless doctors and internes. (2) The abuse of opportunities by careless doctors and externes. That any great harm comes from the free treatment of the folk who can pay, I doubt. . . . I think it more than made good, from the point of view of the public good, which is the only point of view that we can take, by the physical, psychical and educational good done by the dispensary, even for rich patients. I do not believe you can surely weed out the rich, either, by any spotting process."

In seeking the truth which lies somewhere on the middle ground between these extremes, our first question may be as to the facts of the case. What *facts* about dispensary abuse do we know, or what facts should we know, in order to form reliable judgments?

We may thus ask two questions: (1) What investigations have actually been made of the social or financial condition of dispensary patients? (2) What is the present practice of dispensaries with reference to the exclusion of patients from treatment?

Facts Known About Dispensary Patients.—At the International Conference of Charities, Correction, and Philanthropy, 1893, in the Section on Hospitals, Dispensaries, and Nursing, Mr. Charles C. Savage[3] reviewed the history of dispensaries, and stated that one-quarter of the population of New York City were receiving dispensary aid (present statistics do not indicate such a proportion). Mr. Savage based this statement on an investigation which he declared had been conducted by the New York Charity Organization Society. From the ninth annual report of this organization (page 26) it appears that, in 1884, "this society undertook to examine for the German Dispensary, the ability to pay for treatment of such of its applicants as were referred to us, with the following result: 43 per cent. were found able to pay, 27 per cent. were found unable to pay, 30 per cent. gave false or mistaken addresses."

"Each year as it became more widely known that the dispensary availed itself of our investigations, applications from those who could well afford to pay for advice and treatment diminished, until in 1889 the following very different results were reached: Those able to pay declined from 43 to 23 per cent. Those giving false addresses or other evidence of deceit fell from 30 to 25, and correspondingly. Those entitled to the benefits of the dispensary, after thus sifting out the imposters, increased from 27 to 52 per cent."

Inasmuch as the Charity Organization Society did not investigate all the applicants at the German Dispensary, but only such cases as were referred to it—which unquestionably were the doubtful cases—we can in no way estimate the real meaning of the figures which they reported. As will be seen, an investigation of one thousand cases conducted in 1910-11 led to an entirely different conclusion.

Dr. Shrady's attack, already quoted, was by no means the first of its kind,* and did not find the dispensaries without defenders. The rapid growth of these institutions in the metropolis, however, led to considerable agitation, with the result that the well-known law licensing dispensaries throughout New York State and placing them under the general supervision of the State Board of Charities, was enacted in 1899. Besides requiring certain items to be annually reported, records kept, and a registrar on duty at every dispensary—these really being highly valuable features of the law—this legislation prescribed a form which applicants for treatment had to sign, attesting their income, etc., and also required that the penalty for false representation should be printed upon the admission card given to every patient. No violations of this law appear to have been prosecuted during the fifteen years since its enactment.

In 1903 the Hospital Association of Philadelphia caused an investigation of dispensary patients to be made, but I have not been able to obtain a copy of the report. In 1905 a symposium on the subject was published in the *Boston Medical and Surgical Journal*. Dr. George W. Gay[4] sent out at this time a questionnaire to more than 400 physicians in Boston and vicinity. A large majority of the three hundred odd answers which were received stated that, in the opinion of the physicians, medical charity was abused in the hospitals and dispensaries in Boston, and that it was practicable to correct it. Such a questionnaire, of course, collected only opinions and furnished no *facts* regarding the extent or character of abuse, nor concrete suggestions how corrections should be made.

In 1907 the Chicago Medical Society appointed a "Committee on the Abuse of Medical Charities," which secured co-operation from the Associated Charities of Chicago, and presented a report.[5] This indicated that, out of fifty-five dispensaries said to be treating approximately 500,000 patients a year, only three instituted any "adequate investigation into the economic capability of their patients." The Committee of the Medical Society, however, made no investigation into the economic capability on its own part.

Dr. W. S. Thayer[2] reported in the same year (1907) the results of the investigation of a committee of the Medical and Chirurgical Faculty of Maryland. This, like Dr. Gay's report, was based on consultation with physicians. The *Journal of the American Medical Association*, commenting editorially on this report, said: "It would seem to be more to the point if an exact tabulation of Baltimore dispensaries had been made."

Such a tabulation on an extended scale was carried through in 1910 by the Medical Society of the County of New York,[7] which employed Miss Anna Moore, Ph.D., an investigator trained in the work of the New York Charity Organization Society, to study a thousand cases selected at random from the books of thirteen dispensaries in Manhattan. Miss Moore visited the homes of these patients, but was unable to locate two hundred and twenty-five out of the thousand. The tables submitted by her indicate that of the seven hundred and forty-five patients whom she located and whose financial conditions she studied, six hundred and seventy-two, or 90 per cent., were "worthy of free treatment." The remaining seventy-three, or approximately 10 per cent., seemed "Able to pay for medical treatment under ordinary circumstances. But the margin over and above fixed expenditures seems in most cases so slight that in illness demanding continued treatment or the services of a specialist, to pay a physician would mean for them serious deprivation or the incurring of a debt from which afterwards it would be difficult to escape. In fact, in almost every one of these cases, there seemed a very reasonable doubt as to how the case should be regarded."

Of the two hundred and fifty-five cases which could not be located at the addresses given, Miss Moore estimates that the addresses were probably given incorrectly with intent to deceive in thirty-two cases, or 12½ per cent. In the remainder, the failure to find the patients was due to incorrect transcription at the dispensary of name or address (estimated at 34 per cent.), and to the moving of patients or families between the time their address was recorded at the dispensary and the time Miss Moore's visit was paid.

At the Boston Dispensary studies were begun in November, 1911,[7] and have since been pursued, covering altogether five groups of patients, 1,881 in all. The primary purpose was, of course, not to estimate the amount of "abuse," but to ascertain how facts as to social and financial conditions of patients could be obtained most accurately and economically, and whether standards could be formulated for judging the eligibility of patients for admission. Incidentally these studies have led to the conclusion that the percentage of persons able to pay private physicians for the medical services which they need is very small among the applicants at the Boston Dispensary—not over 2 per cent.*

We may now summarize our answer to Question No. 1, "What *facts* are known about the extent of dispensary 'abuse?' "

So far as can be discovered, only two investigations into the facts of this matter have been made, by studying a representative group of dispensary applicants selected at random. These two studies, conducted respectively in New York and Boston, prominent centers of dispensary work, both lead to the conclusion that the percentage of so-called "abuse" is small. People who can pay for medical service seem to appear rarely as applicants for dispensary treatment.

Local conditions vary, and no dictum based upon two investigations should be applied everywhere. But until facts are forthcoming on the other side, there is no justification for denunciation of "abuse" as an evil largely prevalent among dispensaries.

* Dr. Gurteen, one of the pioneers in the charity organization movement in the United States, in his well-known "Handbook of Charity Organization" (1882), described the dispensary system as a "vast school of pauperism, demoralizing the poor, educating them in improvident habits, and teaching them, in one of the most vital departments of life, to be thriftless and improvident" (page 99).

* Miss Moore's estimate of 10 per cent. was in her own opinion a maximum rather than the probable figure for the proportion of "abuse" among the 745 patients whom she studied. Some of the details of the Boston Dispensary studies will be published in a separate paper.

The majority of statements which have been published upon this matter are based upon impressions of individual cases without reference to the proportion which these cases bear to the total group of dispensary applicants.

Present Practice of Dispensaries in Admitting Patients.—At the present time many dispensaries or out-patient departments of large size are without an effectively worked-out and well-centralized organization, and it is a natural consequence of this condition that systems of admitting new patients are unstandardized, even haphazard. There exist large dispensaries and out-patient departments which make substantially no inquiry of the applicant beyond that necessary to make the elementary clerical items of record and to pass him to the appropriate clinic. At the other extreme are institutions in which careful inquiry is made of every patient before an admission card is issued.

In middle-sized cities the point of view of the local practitioner is often more effectively felt by the chief hospitals than it is in the largest communities. The objections of local practitioners to so-called "dispensary abuse" have, in fact, brought about the most marked reactions in communities of middle size, such as Providence, Cleveland and Detroit. At the Rhode Island Hospital, about 1900, Dr. John F. Peters[9] established a system of inquiry of each applicant at the out-patient department. This system, administered by a clerk of long acquaintance in the city of Providence, involves an investigation of each new applicant by searching the tax books of the city, as well as by questioning the patient.

In New York the Dispensary License Law of 1899, already referred to, had as one of its avowed objects the prevention of dispensary "abuse." The State Board of Charity was given the very important authority of prescribing the record forms to be used in carrying out the law. As a matter of fact, it is doubtful whether the law, as a repressive and punitive measure, has been effective in preventing the entry of patients into dispensaries in New York City who really wished to get medical service free, while aware that they could pay for it. Such patients are very few in any case. It is undoubtedly true, however, that the requirement of a registrar has been of great benefit, if for no other reason than that it necessitates a person responsible for keeping the elementary statistics of every dispensary in the manner prescribed by the State Board of Charity. In most dispensaries in New York the number of patients is far too great to receive any thorough examination in the time one registrar can give to each individual. It is nevertheless true that *the introduction of some system is a good thing* in itself. The New York law has somewhat stimulated dispensary efficiency, but its effect upon dispensary "abuse" has been chiefly indirect. Doubtless this is largely because the amount of so-called "abuse," as shown by Miss Moore's investigation, is and probably always has been relatively small.

In Cleveland, Ohio, the subject of dispensary "abuse" has received considerable discussion, and, what is more rare, some elucidation. Dr. H. J. Gerstenberger,[10] at the well-known Babies' Dispensary, has had a definite system of inquiry of the financial condition of each new patient since 1907, the information gathered at the admission desk being checked by the visit of the nurse to the baby's home made within a week or less after admission.

Dr. A. R. Warner,[11] in organizing the Dispensary of Lakeside Hospital and Western Reserve University, has made one of the few distinctive contributions to the theory and practice of dispensary management and to this special problem of "abuse." In his address before the Academy of Medicine of Cleveland, October 13, 1911, Dr. Warner specified nineteen "abuses" of a dispensary. Of these the treatment of too prosperous people was only one. Three others of Dr. Warner's list were: The abuse of the dispensary by outside doctors, the use of dispensary patients as merely clinical material, and the prescription of treatment which cannot be followed by the patient, owing to lack of opportunity or funds.

After thus throwing down the gauntlet to the medical profession of Cleveland, Dr. Warner took up the constructive task of making the admission desk at Lakeside Dispensary fit the demands of his local community. In his article in the *Journal of the American Medical Association* Dr. Warner outlines the system of classification which he adopted, and which he believes to have been successful at Lakeside. Dispensary patients are grouped by him into four classes: (*a*) Suitable for admission for treatment in any department until admission is revoked. (*b*) Suitable for admission in any department for the current sickness only, any other sickness requiring another interview with the admitting officer. (*c*) Suitable for admission for major or special surgery, or for any chronic condition for which the patient cannot be expected to pay the ordinary fees for the treatment needed. (*d*) Suitable for admission for special examination or consultation only (*e.g.* *x*-ray, Wassermann) no treatment being given.

There can hardly be any question that the classification made by Dr. Warner is useful in deciding whether and how a patient should be admitted. The extent to which these definite classes can be incorporated as part of the routine of a dispensary is another matter. Local conditions would affect this considerably. It is much to be desired that Dr. Warner's scheme be now tried out by several dispensaries, particularly in cities of moderate size possessing only few such institutions.

In 1913 a questionnaire, sent out by the writer under the auspices of the American Hospital Association, included the following inquiries on the subject of dispensary abuse: "What is your system of investigation of each new patient to prevent abuse of medical charity? What is your standard of exclusions, *i.e.* what classes of patients are in practice excluded? How many patients of the total number applying for treatment were thus excluded last year?"

Of seventy-six institutions, mostly very representative ones, which responded to this questionnaire, only thirty-six stated that any applicants had been excluded. Some of the remaining forty may have forgotten to answer the question, but we may probably infer that in most of the forty cases, not much inquiry is made of applicants, and that few are excluded. The thirty-six institutions which answered the inquiry positively, treated approximately 520,000 out-patients in 1912. One of the thirty-six reported that it excluded 20 per cent. of the applicants,* one other reported 12 per cent. excluded,

* The Superintendent of the institution which, in 1913, reported this high percentage, writes, a year later, as follows: "The high percentage of cases turned away (in the report of last year) was due to the fact that the dispensary was reorganized and rebuilt, and at-

another 8 per cent. Five of the thirty-six institutions reported between 2 per cent. and 5 per cent. of applicants excluded; eight sent away between 2 per cent. and one-half of 1 per cent., and twenty-one excluded less than one-half of 1 per cent. Out of the 6,000 "new patients" applying for treatment at the morning clinics of the Boston Dispensary during three recent months, thirty-three were excluded because they were believed "able to pay."

We may now summarize our answer to Question No. 2, the extent to which, in actual present practice, dispensaries reject applicants for treatment:

The average dispensary has not established a thorough system of examinations at the admission desk. This is partly because most dispensaries are administratively weak in general, and, therefore, in this point also; but the chief reason is because dispensary "abuse" is not really prevalent enough to make it worth while to do much about it.

Facts have been secured from a representative number of well-administered dispensaries which *do* maintain systems of examination of patients.* In no case, however, are as many as 10 per cent. excluded because they are believed "able to pay," and in five-sixths of the cases the proportion excluded is less than 2 per cent.

The actual practice of dispensaries in a number of cities thus leads to the same conclusion as the investigations previously referred to, namely, that while "dispensary abuse" has often been made a big problem in discussion, it is usually a small one in reality.

The Broad Problem Behind "Abuse."—The subject which has been briefly surveyed in this paper bristles with deeper questions than have been touched. What is to be done with those who are rejected by the charitable dispensary? Is the need of the community met to-day, by private practice, in many specialties where the cost of service is high? The wealthy can pay for whatever they require; the poor can secure the same physicians as the wealthy, at charitable hospitals and dispensaries; the middle classes, constituting in numbers a majority of the population, cannot obtain the aid of specialists (by this term internists, surgeons, and pediatricians are meant, as well as oculists and laryngologists). The problem of dispensary "abuse" is merely one phase of the much larger social question: How shall the majority of the population, self-supporting and determined not to fall below the poverty line, receive medical service on the best standards of modern medicine, which require laboratory facilities and specialists' service inaccessible in most private offices except at high prices?

We may also ask for light upon such questions as: What standards, if any, can be devised for judging applicants for medical treatment? What procedure, on the part of a dispensary admission desk, is most efficient and economical in attaining the desired ends? Is the exclusion of a minute fraction of applicants a sufficient justification for a more or less expensive service at the desk, or can such a service render constructive benefit to the patients *who are admitted?* These administrative questions must be left for another paper. Dispensary "abuse" will for a while, at least, continue to be a bugbear; but it must not be permitted to be a barrier in the way of improving dispensary efficiency. Those who are responsible for the medical work or for the administration of out-patient departments and dispensaries, cannot ignore the discussion about dispensary "abuse"; but they must not allow it to dominate. Of one principle they may be sure: The out-patient department or dispensary which holds before itself as its prime duty the promotion of efficiency, will not have to worry much about the prevention of "abuse."

tracted to it a large number of men employed in automobile works and their families. Hence the 20 per cent. turned away during the period following reorganization. . . . In the Annual Report, forwarded to you under separate cover, you will note that the social worker turned away 1 1/3 per cent. of the cases. This simply covers the cases referred to her by the admitting officer, who could not decide the standing of these cases at the time of their application. In addition to this number, the admitting officer referred back to private physicians 2 per cent. of first applicants. This dispensary is thus now rejecting 3½ per cent. of the applicants."

The reason for rejecting patients at many institutions is not, by any means, only because they are believed to be able to pay physicians. At least half of the cases at the institution reporting 8 per cent. excluded are turned away because they are at the time of their application under treatment at another institution. In cities with several dispensaries this factor accounts for a considerable proportion of the number who are reported as not admitted.

* The establishment of such systems has often been largely for other reasons in addition to the "elimination of abuse."

SYPHILOPHOBIA.

By DOUGLASS W. MONTGOMERY, M. D.,
San Francisco, Cal.

It has been said that no physical torture is equal to the mental anguish of melancholia, and one of its aggravated forms is syphilophobia, combining as it does the sense of shame with that of personal uncleanness. On account of the publicity recently given to venereal diseases it seems to me that this affliction is becoming more frequent. The following case is an excellent example of the trouble, and brings out prominently many of its characteristics.

A man engaged in a sedentary, studious occupation, thirty-eight years of age, and unmarried, called for advice May 2, 1910. He said that he acquired syphilis in 1905, again in 1908, and again in 1909, and two days previously a sore had appeared on the mucous surface of the lower lip, accompanied by sore throat and headache. When questioned closely he admitted that these were the only symptoms constituting the previous so-called syphilitic infections.

The patient was a rather spare, dark complexioned man of a serious melancholy type. He was the kind of individual whom the older physicians with their ideas of humors would have designated as being of bilious temperament. His vocation, as above mentioned, was sedentary, and he was naturally disinclined to take active exercise. He had a heavily coated tongue, flatulent dyspepsia, and frequently had vertigo to the extent of almost falling. The area of liver dullness was somewhat enlarged, and although he had a movement of the bowels each day, the dejections were scanty. His urine was of rather low specific gravity, but otherwise normal. He had at times pain in the right great toe, and complained of headaches as of the bones of the skull. He had a small patch of seborrheic eczema on the left cheek, that had appeared at the same time as the herpes on the lip. He had gone through the usual seral and spirochetal examinations with negative results.

As far as the lesions on the lip were concerned, the present examination, the history, and the subsequent attacks showed them to be herpes, an affection to which men of his temperament and digestive frailties are particularly disposed.

The basis of herpes simplex is a constitutional disposition, and the immediate cause of an outbreak may be due to any one of a multitudinous variety of irritants. As has been mentioned, digestive disturbances, such as this man had, are frequently a cause. Sugar is another excitant, and in some people the different fructoses are varyingly noxious. I know one man, for instance, who is fond of black figs, and during their season gets a sore mouth if he indulges. Another patient has a similar experience during the cantaloup season. With some men the irritation of cohabitation will cause herpes progenitalis, and these patients are especially apt to suspect that their trouble is venereal. Both menstruation and pregnancy are causes of outbreaks in women. Climate has also an influence. A patient of mine, who had repeated attacks of herpes progenitalis while living in San Francisco, went to Alaska, and from the time he left Portland on his way north until his return to Portland on his way south, a full year, he had no outbreak. On resuming his residence in San Francisco, the old attacks reappeared with their former frequency. As is well known bacterial infections, such as those that cause la grippe or pneumonia, will cause an outbreak of herpes.

The patient's mental condition was aggravated by an interesting circumstance. The attacks of herpes that he imagined to be syphilitic infections so preyed on his mind that his relatives and a doctor conceived the idea of telling him that he was correct in his surmise. They thought that by giving him a course of treatment for syphilis he would imagine himself cured, and that the difficulty would be solved. On the contrary, however, with a new herpetic outbreak, his deplorable mental condition was aggravated, and this was his condition when he sought my advice.

The nature of herpes was carefully explained to the patient, and he was put upon a rational diet and suitable medication, but each new attack brought out an expression of the same mental anguish. Finally on March 21, 1912, he came to the office with almost a triumphant look on his face, saying that he would finally satisfy me of the correctness of his assumption that he had contracted a luetic infection. He stripped and showed a beautiful herpes zoster of the right lumbar region. Five days previously I had seen some bright red papules in this region, but thought they might be flea bites. That night the patient was kept awake by pain in this locality, and following this the present eruption had developed. It was now a typical manifestation of the disease, and, as is frequently the case, on the maturation of the eruption the pain was almost gone. The lymph nodes in the right groin were enlarged and somewhat tender. A few days before the appearance of the zoster the patient had been

exposed to infection. On account of his naturally pessimistic temper the patient was certain from the occurrence of the eruption, the enlargement of the lymphatic nodules in the groin, and the exposure to infection that he had contracted syphilis. I was able to show him that the enlargement of the regional lymphatic nodules is an almost constant accompaniment of herpes zoster, and as for the eruption itself it was so characteristic that I urged him to see independently any well-informed physician to confirm the diagnosis. This was a complete refutation of his position, and after this I heard no more about syphilitic infections.

In regard to the demeanor a medical man should assume in such cases, I consider it a great mistake to yield to the patient's insistence, and to admit the presence of an infection that he does not really believe to exist. It can only lead to disaster, and any wavering is fatal.

In order that the physician may convince the patient of the correctness of his diagnosis he must be familiar with the diseases that may simulate syphilis, even the apparently insignificant ones, such as herpes simplex. These patients read up most industriously on their particular hobby, and although they do not usually offensively dispute the several points they most ingeniously and persistently advance in support of their position, they tend to remain unconvinced in spite of whatever their physician may say to the contrary. I do not know anything more wearisome or demanding more patience than the management of such a case. Under such circumstances one often feels that John the Baptist was the wisest of all the orators as he went out into the desert and preached to the eyeless winds. In the present instance after nearly two years of varying success and failure, the fortunate accident of an intervening herpes zoster rid the patient of his delusion.

323 Geary Street.

Medicolegal Notes.

Medical Services Rendered in Emergency—Reasonable Value.—The president of a corporation, in the course of the trial of an action against the corporation, fell from his chair to the floor of the courtroom, unconscious. A physician who was testifying for the plaintiff offered his services, and administered first aid. This was continued for from 15 to 20 minutes, when it was decided that the patient was dead. A day or two after the physician sent a bill for $500, which the deceased's executors refused to pay and the physician sued therefor. The deceased left a very large estate, and the admission of evidence as to its value was objected to by the defendants. It was held that this evidence was properly allowed and properly taken into consideration, and that, together with the experience of the physician as such, and the nature and difficulty or easiness of the case, and what was considered by him and by other physicians an ordinary or reasonable charge for the services, were the proper elements upon which a judge or jury might act in fixing the value of the services. The services performed here were not difficult. They did not require any special degree of skill or knowldge, nor were they of such a character that it required a physician of years of experience or study to perform them properly. They consisted of what a medical student could perform as well as a physician of years of experience. Two physicians testified for the plaintiff that $500 was the value of the plaintiff's services, while experts called for the defendant placed the value at from $10 to $15; one stating that a fair charge would be from nothing up to a maximum of $15.

On the question of who was liable for the services, it was held that the case fell within the rule that one who becomes ill, and through unconsciousness or otherwise becomes incapable of acting or deciding for himself, is liable on the theory of an implied contract or promise that, having received the benefit of necessary medical aid and attendance, he must pay for them, no matter by whom the physician was summoned to perform them; and from the necessity of the case any one is authorized to call a physician to treat him, without liability on the part of the person so calling the physician.

The attention of the court was not called to any case in the state of New York where the question was presented as to the right of a physician to recover from a patient or his estate for services rendered to him while unconscious, or in extremis, when called by a stranger or spectator to treat the patient, or where the physician acts of his own volition; and counsel agreed there was none in the state that could be cited for either the plaintiff or the defendants. The court held that a physician's right to recover on an implied contract was the same in either case. Duty requiring him to give his aid, and having given it, he may expect payment by reason of the promise created by law from the patient to do so, although he never asked for the aid or consented to it being given. In an emergency case, requiring immediate attention to save life, the physician when called, or when he volunteers his services, should not stop to inquire by whom he will be paid, or to make it known that he expects to be paid. It would be an inhuman act to do so or to give that subject a thought; and, while the question whether or not the services were intended to be gratuitous is one of fact, the plaintiff may rest his case upon an implied promise and can recover, unless it is shown either that there was no intention to charge or that the credit was extended to a third person. Offering his aid does not establish the fact that he intended his services to be gratuitous. In the present case the intention to charge the deceased or his estate was sufficiently established by the fact that a day or two after the plaintiff rendered the service he made a claim and sent a bill for it to the estate.

If a distinction must be made in the application of the rule as to liability of persons becoming unconscious by an accidental injury or otherwise in a large city, having free ambulance service and free hospital treatment, and elsewhere, where there is no such free service and treatment, then there still remains the question whether, in a large city, such immediate attention was required, and this is a question of fact, involving the consideration of the nature of the disease or of the accident, the time and place when unconsciousness occurs, the time that must elapse before other or free medical treatment can be obtained, and other considerations depending upon the circumstances in each case. Here the facts showed that immediate attention was necessary, as death occurred before the ambulance surgeon arrived.

Taking into consideration the easiness of the services, the occasion and circumstances under which they were performed, and all the evidence in the case, the court gave judgment for $15 as the reasonable value thereof. —Schoenberg vs. Rose, 145 N. Y. Supp., 831.

Proceedings for Revocation of License—Jurisdiction of State Board of Health.—Proceedings having been commenced before the Kentucky State Board of Health for the revocation of a physician's license, the defendant sought to enjoin the board from proceeding in the matter on the ground that the statute under which the board acted was void. The statute, Ky. St., §2615, authorizes the revocation of a physician's license for fraud in obtaining the same, for commission of a criminal abortion, or conviction of a felony involving moral turpitude, for chronic or persistent inebriety, or addiction to a drug habit to an extent which disqualifies the physician to practice with safety to the public, and for "other grossly unprofessional and dishonorable conduct of a character likely to deceive or defraud the public." It was held that the ground quoted should be construed to mean other unprofessional and dishonorable conduct than the acts previously specified, also involving moral turpitude, and, as so construed, the statute was a valid exercise of the police power. The proceeding before the board was not judicial, but purely administrative. The board was not authorized to act arbitrarily, but only on reasonable grounds, and if it did act arbitrarily, and there was no other adequate remedy, the courts would intervene to protect the private right of the physician to continue his practice. The petition for injunction was therefore dismissed.—Forman vs. State Board of Health, Kentucky Court of Appeals, 162 S. W., 796.

THE WOUNDED IN NAVAL WARFARE.

SHORTLY before the outbreak of the present war there was read a paper on this subject before the Section of Naval and Military Medicine and Surgery of the British Medical Association, by Fleet-Surgeon D. Walker Hewitt. At that time no one dreamed that the principles enunciated in this address would soon be put to test by a conflict in which the most modern methods of scientific slaughter are demanding the keenest resources of this, the most brilliant era of surgical history. Of particular significance is the fact that although the English army surgeons have had in recent years a vast amount of experience, nevertheless their naval brethren have never had an opportunity of testing their first-aid and other methods under actual conditions of modern warfare.

The conditions of naval warfare are entirely different from those that obtain on land. The army medical officers, in addition to the routine care of the sick and wounded, are compelled to take cognizance of various matters of hygiene and sanitation incidental to fighting on land, and of the danger of epidemics and a doubtful water supply. In contrast with these duties the naval surgeon must contend with the lack of space; with overcrowding; with the difficulties of transportation from inaccessible positions; and with the absence of Nature's germicides, sunshine and fresh air. At the same time the naval medical officers must carry on their arduous work in such a way as not to interfere with or hamper the fighting machine. No amount of zeal and ingenuity can convert the man-of-war into a floating hospital, and all of the arrangements for the immediate relief of the wounded in naval battles must be subordinated to fighting efficiency.

The most essential requirement in this relief is the presence on board ship of a first-aid party every individual of which should have a correct knowledge of how to carry a wounded comrade and where to carry him. The real first aid during action should, with rare exceptions, be carried out in the dressing stations under the eye of the surgeon. If first aid is rendered by the naval ambulance corps at the spot where the men fall at their guns, grave dangers are incurred. The greatest of these, which played such grim havoc in the old days of the cockpit, is sepsis, with its accompaniments and sequelæ. Lacerated wounds, burns, and scalds are especially prone to sepsis, and everything depends on the primary treatment of these cases.

On a battlefield the wounded men are scattered over wide areas. First aid where they fall is a necessity inasmuch as on account of the nature of the wounds inflicted by the bullet or bayonet hemorrhage is common and demands the immediate use of the tourniquet. On the other hand, in a naval engagement the character of the wounds is so different that cases of primary hemorrhage are rare. The shell wounds which lacerate the tissues are not as a rule accompanied by bleeding. The paramount duty of the first-aid party on a warship, therefore, is to carry the wounded in a proper manner to the surgeons and the dressing stations of the ship. The most important duty of the surgeons is not to do major operations but to administer the essential emergency measures of relief. This work should not be left to the first-aid party. It is impossible for the bearers to examine the nature of the wounds while the fight is going on around them.

One of the greatest difficulties that confront the naval surgeon to-day is that owing to the numerous bulkheads and armored hatches, the transport of the wounded is rendered quite difficult. But at the same time this compartment system may diminish the casualties under armor and the great bulk of the wounded will be in the exposed or semi-exposed parts from which access to the dressing stations is still easy. The application of surgical dressings by the bearers should be permitted only when the casualties are heavy and the dressing stations are filled, and when the wounded are in positions from which they can be removed only slowly and with great difficulty, such as the engine rooms or tops. Owing to the restricted space on a warship the stretcher has a limited field of usefulness. One or two men unencumbered by a stretcher can, if properly trained, carry a comrade up or down ladders or through narrow spaces. The methods of "manhandling," as it is technically called, are regarded as of more importance so far as first aid is concerned, than the niceties of bandaging and other surgical details.

It may seem like a refinement of modern warfare, undreamed of in the days of Admiral Lord Nelson, that before going into action the crew should, if possible, scrub their bodies well with soap and water and wear clean or sterilized clothing. The dressing stations, of which two or more are fitted up with great care on the larger ships, should be in a position protected by armor and not too hot. Hewitt is inclined to believe that in the smaller ships the wounded should be distributed over a larger number of first-aid stations than in the big vessels where ample protection can be provided. The danger of a single shell to all the wounded and the medical staff when they are huddled together in an unprotected space was illustrated in the Japanese ship *Hiyei* in the battle of the Yalu. The sooner the wounded are removed from the fighting ship the better for all concerned.

An important question in naval warfare is the fresh air supply to the dressing stations. In spite of supply fans, when the guns are at work and the

enemy's shells are bursting around on the decks and possibly between decks, those below are not safe from the suffocating effects of lyddite and of charred and burning paint. It is suggested that a supply of oxygen should be carried in time of war. Aseptic or antiseptic methods or a combination of both must be adopted as considered necessary. Experience has shown that lacerations from shell wounds, burns, and scalds form the great bulk of the serious cases, and the primary danger of all three is summed up in the one word "shock." Sepsis and secondary hemorrhage are important sequelæ but at this stage the patients should be in hospitals on shore or on hospital ships. The performance of major operations during the action is out of the question. Men who are slightly disabled should be restored to their stations as soon as possible. When the action is over the wounded should be promptly transferred to hospital ships or land hospitals, partly for their own sake and partly for the sake of the fighting efficiency of the man-of-war.

THE TREATMENT OF UNCOMPLICATED TUBERCULOUS FOCI IN BONES.

SHALL we be radical or conservative in the treatment of pure tuberculous infection of bone? This question is almost as old as modern surgery itself, and we are but little nearer the ultimate solution of the problem today than we were a decade ago, though the trend of opinion seems slowly but surely setting toward the use of the more radical measures. A tuberculous focus in bone, as elsewhere, may become encapsulated and remain quiescent for a long period of time; but there never can be absolute assurance that the barriers will not some time be broken down and a mixed infection inaugurated which will finally result in extensive destruction of bone with, perhaps, invasion of neighboring joints and soft tissues.

One of the pioneers in the recognition of the value and in the practice of radicalism in the treatment of tuberculosis of bones and joints, the late A. M. Phelps, often said in his lectures "limit the length of your incision by the length of the patient, if necessary, but thoroughly eradicate the focus if possible." This was, of course, an intentional overstatement designed to impress upon the class that the source of the trouble must be reached and removed, and that half-way measures were often worse than useless. The large incision, thorough curetting, the application of 95 per cent. carbolic followed by 95 per cent. alcohol, careful antiseptic dressing, and attention to details brought him many brilliant results in early tuberculous bone involvements. Recently recruits to the more radical methods of treatment have been appearing in increasing numbers; and among these should be particularly mentioned Ely, Sherman, and Huntington of San Francisco. Ely, while a believer in conservative methods in the treatment of tuberculous bone and joint disease during the early years of life, advocates radical measures when adults are affected. Sherman, after thoroughly curetting, follows Phelps in the use of carbolic acid and alcohol, then adopts Mayo's procedure as advised in the removal of a tuberculous kidney, namely, filling the cavity with salt solution and closing the wound by layers.

Huntington (*Annals of Surgery*, June, 1914) makes a strong plea for the radical treatment of uncomplicated tuberculous foci in bone. As he says, "The objects to be obtained by early, direct interference are: (*a*) Permanent cure by elimination of the focus; (*b*) reduction of time of treatment from years to months; (*c*) prevention of complications, such as abscess formation, mixed infection, disintegration of bone and joint structures, crippling deformity and loss of function; (*d*) avoidance of systemic invasion and loss of life." After thoroughly exposing and clearing out the focus he packs the cavity with camphor-phenol gauze. After a few days the amount of gauze packing is reduced, then entirely dispensed with, and finally the bone cavity remaining may be filled with Beck's paste or the Mosetig-Moorhof wax. The wound may then be closed and fixation secured by a rather loosely applied plaster-of-Paris dressing. Sixteen cases are referred to in which he carried out this procedure, the results being in general much better than in similar cases under the more conservative methods of treatment; and we must agree with him that "to leave an accessible tuberculous bone focus, whether isolated or not, to smoulder until provoked to renewed activity at a later period is without justification, and seems to do violence to surgical principles. Certainly such a course in the presence of an osteomyelitis due to ordinary pathogens would be reprehensible. Can it be otherwise than true that thorough removal of the focus and surrounding tissue is as logical for tuberculous as for ordinary osteomyelitis?"

CAUSATION OF DIABETES IN CHILDREN.

IT is not rare for children of school age while in the full bloom of youthful vigor to develop a malignant type of diabetes. In this country at least these cases seldom come to autopsy, nevertheless there is every reason to believe that the actual disease is pancreatitis, the diabetes being the clinical expression. Although these children are doomed from the start, a knowledge of the causation of the pancreas lesion might lead to the use of prophylactic measures or at least prepare the parents for the possibility of a tragedy. In rare instances pancreatitis has been due to a metastasis of mumps, and there is always a possibility that not only mumps but some of the other infectious children's diseases may so cripple the pancreas that it may become infected from the intestine, or perhaps through the blood as a result of tonsillitis. As mumps frequently appears in children at a relatively late period, it is certainly well to examine the pancreatic region, the stools and urine, not only during the disease, but occasionally at later periods, in order to make certain of the integrity of the organ.

In the abstract columns of the MEDICAL RECORD for September 5 was an account of a very serious pancreatitis syndrome described by Dracinski and Mehlmann (*Deutsche medizinische Wochenschrift*, July 30) in connection with mumps. Of hundreds of victims, but five presented this severe complica-

tion, but this takes no account of possible mild implication of the organ. The diagnosis of pancreatitis had not of course the corroboration of autopsy, and it is regrettable that the authors did not mention the stool finds, which should have clinched the matter.

Antityphoid Vaccination in the British Army

In an appeal issued by the British War Office to the profession in England it is pointed out that antityphoid inoculation remains unfortunately on a voluntary basis in the British Army, and the benefit of its protection to the troops can be secured only by persuading the officers and men as to the reality of the danger of typhoid fever and as to the protective value of the vaccine. The following facts relating to antityphoid inoculation are emphasized: No army in recent wars has escaped typhoid fever, which in several campaigns has killed more men than the enemy. In the South African war, for instance, there were 57,684 cases of typhoid fever, of which 19,454 (33 per cent.) were invalided and 8,022 (13.9 per cent.) died. The deaths from typhoid fever exceeded the total number of men killed in action. About 93 per cent. of the British garrison of India have been protected by inoculation, and typhoid fever, which used to cost the troops in India from 300 to 600 deaths annually, was last year responsible for less than 20 deaths. Inoculation was made compulsory in the American army in 1911 and has practically abolished the disease; in 1913 there were only three cases and no deaths in the entire army of over 90,000 men. Arrangements were made some years ago at the Royal Army Medical College to prepare and maintain a very large reserve of typhoid vaccine, and from this reserve there have been issued since mobilization more than 170,000 doses for the use of the troops.

Castration and Mammary Carcinoma.

Removal of the ovaries in the hope of favorably modifying the course of inoperable cancer of the breast has been performed a number of times since its first introduction by Beatson. We are not aware that this material has ever been collected and analyzed, but there is no doubt that castration does act as a palliative in some cases. Before the Northeast German Gynecological Society last spring (*Deutsche medizinische Wochenschrift*, July 23), Lampé reported that, after a considerable experience with Beatson's method, he had extended its scope by castrating in operable cases as a preliminary to amputation of the breasts. During the interval between the two operations he noted very prompt evidence (even within the first few days) of involutionary changes. The tumors became distinctly smaller and softer and a few outlying nodules in the skin vanished. In one case the cancer was almost cured, having undergone atrophy within four months until it was but a third of its original size. In this case the greatly enlarged axillary glands underwent complete involution. Benthin, who discussed the report, believes that the results indicate the existence of an endocrinous relationship between the ovaries and mamma. The more or less marked atrophy of the breasts which is so often observed to follow complete ovariotomy tends to confirm this belief.

News of the Week.

The American Red Cross Ship.—By the time this paper is printed the former Hamburg-American liner *Hamburg*, renamed the *Red Cross*, and painted white with a red band running lengthwise of her hull will probably have sailed from this city for Europe. The ship is officered by retired officers of the U. S. Naval Service and manned by a crew of American citizens. She carries ten hospital units, each composed of three surgeons and a staff of twelve nurses. The ship will touch first at Falmouth, where six surgeons and twenty-four nurses—two units—will be landed for England. At Rotterdam will be landed two units for Russia, two for Austria, and two for Germany. The units for France will be left at a French port. Surgeons and nurses for Servia have been sent in a Greek ship. The surgeons are under the command of Major Robert W. Patterson, Medical Corps, U. S. A. Miss Helen Scott Hay is in charge of the nurses. The surgeons making up the ten units sailing on the *Red Cross* are:

Dr. Reynolds M. Kirkby-Smith, Sewanee, Tenn., director; Drs. John A. C. Colston and M. H. Todd, Baltimore, assistants.

Dr. Rhoades Fayerweather, Baltimore, medical school, director; Drs. Lewis C. Spencer and H. C. Slack, Baltimore, assistants.

Dr. William S. Magill, New York, director; Drs. Philip Newton and Paul M. Zinkham, Washington, assistants.

Dr. Robert W. Higs, Buffalo, director; Drs. Fred W. Eastman, New York, and Henry M. Shaw, Johns Hopkins Hospital, assistants.

Dr. Edward H. Egbert, Washington, director; Drs. Brown S. McClintic, Peru, Ind., and Arthur M. Zinkhan, Washington, assistants.

Dr. Charles H. Sanders, Washington, director; Drs. J. F. Spearman, Baltimore, and Grover A. C. Stem, Washington, assistants.

Dr. Cary A. Snoddy, Knoxville, Tenn., director; Drs. Fred G. Benton of New York, and Walcott Denison, St. Louis, assistants.

Dr. John Bartlett, Chicago, director; Drs. Russell A. Jewitt, Cleveland, and John C. Miller, Shenandoah, Pa., assistants.

Dr. Howard W. Beal, Worcester, Mass., director; Drs. V. N. Leonard and William T. Fitzsimons, New York, assistants.

Dr. Bial F. Bradbury, Norway, Me., director; Drs. R. H. Mann, Knoxville, Tenn., and John Lancer, New York, assistants.

Health of the American Troops at Vera Cruz.—Despite four months of duty in the tropics at Vera Cruz, the American soldiers and marines have maintained a very satisfactory average of health. The sick rate for the week ended September 2 was 2.40 per cent. for the army and 1.63 per cent. for the marines. Fifty men were sick in the hospitals and twenty in quarters. Of these, sixty-four were incapacitated by disease, and six by injury. Fifteen cases of malaria were reported. Ninety-seven soldiers remained sick at the end of the week, as compared with 106 remaining sick August 26.

The Death Rate in New York City during the first eight months of this year was 14.16 per thousand, which is 0.3 point lower than the mortality for the same period last year. If this apparently small reduction in the death rate continues it will mean a saving of approximately 1,675 lives during the year. There were more deaths among infants dur-

ing the month of August than in the same month last year. The extreme heat during the first week of August is considered the reason for this increase. In August, 1913, the deaths among infants under one year averaged 60 in every 1,000 born during the month, while this year the figure increased to 67.

Enforcing the Registration Law.—Six indictments and convictions of physicians in North Carolina were secured during the first two weeks in August for failure to comply with the law of the State requiring the registration of births and deaths. The Board of Health has issued a bulletin calling attention to these convictions and notifying the physicians of the State that other indictments will follow unless the law is strictly obeyed by all. The law has been in operation since the beginning of the year and the Health Board says all should now be familiar with its provisions and hereafter no excuses will be accepted from delinquents.

The Medical Department of the University of Alabama.—It is stated, and also denied, that this medical school, now located in Mobile, will this year or next be removed to Birmingham. The reason given for the move is that the city commission of Mobile has failed in its promise to turn over the management of the City Hospital to the University, and has even taken from the university what little authority it formerly had over the hospital. The college is one of the largest in the South, having a faculty of 40 professors and instructors and 150 students. Dr. Eugene D. Bondurant is dean of the institution.

Gifts to Hospitals.—By the will of the late Abby Hause of Philadelphia, her entire estate valued at $5,000 is bequeathed to the German Hospital for the endowment of a free bed. To the Lynn (Mass.) Hospital $10,000 was bequeathed by the late Luther S. Johnson; had he survived his wife the hospital would have received $140,000. The late Mary P. Welcome of Leominster, Mass., provided in her will for a gift of $200 to the Leominster Hospital Association.

The Physicians' and Surgeons' Hospital is the name of a new institution, ground for which was broken in New Haven, Conn., on September 1. The hospital will be for the accommodation of pay patients only, the charge for a bed being from $10 per week in the wards to $75 per week in the private rooms. The attending staff will be organized on a novel plan, as no physician or surgeon will be eligible for election to it who has not demonstrated, by publication in the medical press or by some other actual work done, that he is capable of filling a staff position in an efficient manner. If he becomes a member of the staff he has to write an article for publication in the medical press at least once a year, describing some work which he has personally done or some discovery which he has made. Failure to do this automatically terminates his membership on the staff. It is expected that the hospital will be ready for the reception of patients in about one year.

New Hospitals.—St. Elizabeth's Hospital, Brighton, Mass., was opened for the reception of patients on the last day of August. The building, which has 200 beds, is of cement with a terra cotta roof, three stories high, with wings forming a court in the rear. The basement contains the kitchens and dining rooms for all the hospital attendants. The first floor is taken up with a pharmacy, a surgical outdoor department, a nose and throat department and a nurses' lecture room. The offices are also on this floor. The second floor, besides having most of the wards, has also the maternity department, a library and a recreation room for the nurses. The third floor contains the remainder of the wards and has a chapel, a students' room, and an operating room. The physician-in-chief of the hospital is Dr. John R. Slattery, the surgeon in charge is Dr. John W. Lane.

The Wing Memorial Hospital, Palmer, Mass., was opened for the reception of patients on September 9. The superintendent of the hospital is Miss Margaret Hill, formerly of the Highland Hospital, Fall River. The hospital has no free beds and no medical staff, the charges being from $10 per week in the wards to $25 per week in the private rooms. Any physician may take his patients there, providing for them such medical or surgical attendance as he may desire.

Gifts to Charities.—The Montefiore Home and Mount Sinai Hospital, New York, receive bequests of $500 each by the will of the late Bernard J. Salomon of this city.

The sum of $5,000 is left to Mount Sinai Hospital by the will of the late Moses Weinstein of New York, which also provided that one-half of the residue of the estate, up to $5,000, should go to the New York Institution for the Instruction of the Deaf and Dumb.

The will of the late Jacob Langcloth of New York provides for bequests of $5,000 each to Mount Sinai Hospital, the German Hospital, and the Manhattan Eye and Ear Hospital, and of $1,000 each to the Isabella Heimath and St. John's Guild. The bulk of the estate, which was estimated to amount to more than $10,000,000, is to be used for the foundation of a home to be known as the Valeria Recreative and Convalescent Home. The institution is to be nonsectarian and is to be open to "people of education and refinement who cannot afford to pay the charges exacted at health resorts."

Obituary Notes.—Dr. HASKET DERBY, one of the pioneers in ophthalmology in this country, died at his home in Dorchester, Mass., on August 21. He was born in Boston June 29, 1835, and was graduated in medicine from Harvard in 1858. After a term of service in the Massachusetts General Hospital he spent four years in the study of ophthalmology in Europe. Upon his return he served as surgeon in the army, and at the conclusion of the Civil War began practice in Boston. He retired from practice several years ago. He is survived by his widow, one daughter, and five sons, one of whom is Dr. George S. Derby of Boston.

Dr. CHARLES H. BACON, a former mayor of Lockport, Ill., died at his home in that city after a long illness on August 26. He was born in Albany, N. Y., November 12, 1834. He was a graduate of the Northwestern University Medical School, Chicago, in 1862. He served from the time of graduation to the end of the Civil War as surgeon in the Northern Army, and at the close of the war began practice in Lockport.

Dr. JOSEPH F. ROBERTSON of Steubenville, O., a graduate of the Columbus Medical College, Columbus, O., in 1881, and a member of the American Medical Association and the Ohio State and Jefferson County Medical Societies, died at his home, after a long illness, on August 17, aged 62 years.

Dr. CHARLES MARINER COOLIDGE of North Waterford, Me., a graduate of the Dartmouth Medical School, Hanover, in 1888, died, after a brief illness, on August 12, from heart disease, aged 49 years.

Dr. THOMAS JOSEPH MURPHY of Bangor, Me., a

graduate of the College of Physicians and Surgeons, Baltimore, Md., in 1899, and a member of the Maine Medical Association and the Penobscott County Medical Society, died at his home, after a long illness, on August 14, aged 51 years.

Dr. FRANK ELY OSBORN of McAllen, Tex., a graduate of the University of Nebraska, College of Medicine, in 1903, a member of the State Medical Association of Texas and a member and president of the Hidalgo County Medical Society, was struck and instantly killed by a railroad train while attempting to cross the track in his automobile, on July 30, aged 37 years.

Dr. PHAON D. KEISER of Lehighton, Penn., a member of the Medical Society of the State of Pennsylvania and the Carbon County Medical Society, died at Mahoning, Penn., on August 5, aged 76 years.

Dr. HENRY M. HASKELL of Redlands, Cal., a graduate of the Bellevue Hospital Medical College, New York, in 1878, died at his home, on July 31, aged 62 years.

Dr. WILLIAM I. WOOD, until recently of Massillon, Ohio, a graduate of the Cleveland College of Physicians and Surgeons in 1888, died in Cleveland on August 6, following an operation for appendicitis, aged 56 years.

Dr. ROBERT FRANCIS GIBSON of West Somerville, Mass., a graduate of the Harvard University Medical School, Boston, in 1901, and a member of the American Medical Association and the Massachusetts and Middlesex District Medical Societies, died at his summer home in Hill, N. H., after a long illness, on August 16, aged 41 years.

Dr. DANIEL CAMPBELL ROSE of Stoughton, Mass., a graduate of the Harvard University Medical School, Boston, in 1869, died at his home suddenly, on August 13, aged 76 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

RED CROSS AND AMBULANCE SOCIETIES—HOSPITALS, HOUSES, ETC., OFFERED TO THE WAR OFFICE—A DEMONSTRATION OF RED CROSS WORK—SCARCE DRUGS AND THEIR MANUFACTURE—REPORT OF COMMITTEE OF COMMONS ON PATENT MEDICINES —DR. ADDISON IN OFFICE.

LONDON, August 28, 1914.

YOU will understand that everything seems to be overshadowed by the war and though we carry on our usual avocations, even doctors are so absorbed in day-to-day and hour-to-hour telegrams that they will talk of nothing else. But as you will know as soon as we the pressing news I will merely note some points as to the Red Cross and St. John Ambulance Societies and such like movements. The British Red Cross Society has received since the declaration of war donations from the Australian branch of £5000, a like sum from Sir E. Cassell, and other contributions which make nearly £50,000, and Queen Alexandra as president is daily receiving letters from persons who can only spare small sums. Other assistance is being rendered in most various ways. The Empress Eugenie, who sent £200 to the fund, has fitted a wing of her house for the reception of wounded officers of whom fully trained nurses have volunteered to take charge.

Lord Dunraven has chartered and fitted out a steam yacht as a hospital ship which he will himself command. General Sir Ivor Herbert, Lord-Lieutenant of Monmouthshire, has brought together a committee for coordinating the work of the St. John Ambulance, the Red Cross, and other organizations desirous of establishing supplementary hospitals and convalescent homes—not to supersede in any way local branches on committees of existing societies but to assist in obtaining concentrated effort on definite objects and avoiding overlapping, so as to secure the most efficient results.

The Crystal Palace and Park have been offered to the war office for a temporary hospital for sick and wounded.

So many offers of houses for the use of the sick and wounded or for conversion into hospitals are being made that the war office has been obliged to issue a notice that for the present no more are wanted, but should necessity arise for further accommodation an appeal will be made for it. The admiralty has closed the temporary naval hospital at Grimsby because the number of hospitals fitted out by private enterprise has rendered it unnecessary.

At the Botanic Gardens on Saturday afternoon there was a display of ambulance work provided by a number of Red Cross voluntary detachments for the purpose of affording the public an opportunity of seeing the nature of much of the work of the Red Cross on the field of battle. The display was under the command of Mr. James Cantlie, Surgeon and Honorary Colonel of the R. A. M. C., whose work in this direction is probably well known to you. For the purpose of the demonstration an engagement was supposed to have taken place in defence of one of the Park gates and a number of the defenders, represented by Boy Scouts, wounded. Gunshot wounds predominated, though others were also represented of which one was loss of a hand by explosion of a shell. The Red Cross party went to work with all sorts of improvised materials for bandaging and other help. They constructed a stretcher out of handles of hayforks and carried the bandaged wounded to the clearing hospital. This was soon filled and some of the less grave cases, having been attended to, were removed to one of the rest stations so as to leave room for further arrivals. From the rest stations they were passed on to the stationary hospital and in due course to the base hospital. At both these last there were operating theaters, dispensaries, and field kitchens.

A shortage of the drugs usually manufactured in Germany has caused an excessive rise in prices and the government has appointed a committee of medical men to "consider questions arising in connection with the supply of drugs for curative purposes in the United Kingdom, with special reference to the ways in which the medical profession can assist in effecting economies in the use of these drugs of which the supplies are at present small." No doubt there are many cases in which a plentiful or inexpensive drug may take the place of one that is scarce or costly. But would it not seem more reasonable to seek fresh sources of supply for the temporary deficiency and for the future to rely more on ourselves? There are many able chemists among us who might well seize the opportunity of establishing manufactories of the fine chemicals which they have been content to let us buy from Germany. Want of capital to lay down the plant is generally assigned as the reason if you put the case before

accomplished chemists. To such, I respond, associate yourself with capitalists. This is done in other industries such as the electrical and scientific instrument production and similar cooperation would be equally successful. I am told that the duty on alcohol is another impediment as so much is consumed in the refining of fine chemicals. But now is the time to press the government, which is asking doctors to economize in these drugs, to do their share by remitting this heavy duty on one of the necessities for manufacturing them. If the committee of medical men for considering "the questions arising in connection with the supply" do not secure this remission (already granted them for research work) they can have little influence on the government which appointed them.

The select committee on patent medicines and appliances and advertisements relating to them issued a report on Wednesday evening. The committee held 32 public sittings, examined 42 witnesses, and asked 14,000 questions. One of the recommendations agreed upon is that the administration of the law on advertisement and sale should be under the authority of the Ministry of Public Health when such a department of state is created.

Dr. C. Addison, M.P., whose support of the ministry in the House has for some time marked him out as expecting office has been appointed Parliamentary Secretary to the Board of Education.

The issue of a new edition of the *Pharmacopœia* has been postponed *sine die*,—it is said in consequence of the war. To many the reason assigned does not seem very obvious.

FIFTH ANNUAL SESSION OF THE CLINICAL CONGRESS OF SURGEONS OF NORTH AMERICA.

(From Our Special Correspondent.)

THE evening session of Wednesday, July 29, was as replete with interest as the previous meetings. The attendance was excellent and the many who were present were well repaid for their trouble. Professor Krönig, of Freiburg, should have read a paper on the treatment of uterine cancer by *x*-rays and by radium, but was unable to attend the meeting owing to the fact that he had been called upon to hold himself in readiness for war service. Dr. C. Jeff Miller, of New Orleans, took his place, and as he had recently paid a visit to the clinic of Professor Krönig, gave his views in a paper entitled "A Review of Professor Krönig's Work in the Non-Operative Treatment of Carcinoma." He said that Krönig had given up operative measures in the treatment of early operable uterine tumors as also for advanced cases. Reliance was wholly placed upon radiation treatment. The results of *x*-ray treatment were regarded as superior to those of hysterectomy for fibroids, although in women under 40 myomectomy was undertaken when feasible. It was advisable to extend treatment over a period of three or four months and must be repeated on several occasions. According to statistics collected at Frieburg malignancy developed in only 1 per cent. of fibroids, and even when this happened radiation would cure it. The statements of Professor Bumm that deep-seated cancer could not be influenced by the *x*-rays were not in accord with the experience of Professors Krönig and Ashchoff, who had convinced themselves that undoubted cases of cancer of the stomach had been cicatrized, and that even when there had been secondary growths in the liver complete retrogression had sometimes been brought about. In the Freiburg clinic radium and thorium were used in heroic doses, and a special apparatus had been devised so as not to burn the patient's skin. Krönig was a believer in high dosages of radium strongly filtered as possible remedial and curative agents in the treatment of malignant disease in deep organs. He employed large quantities of radium and thorium from a greater distance than it was usually employed. For example, for carcinoma of the cervix he did not apply radium through the vagina but only from outside the abdomen. He was not in favor of the implantation of radium into actual growths. Dr. Miller confessed a certain amount of skepticism as to the results of Krönig's methods of treatment, but highly praised his enthusiasm.

The next paper read was by Dr. J. F. Percy, of Galesburg, Ill., on the "Treatment of Inoperable Carcinoma of the Uterus by Application of Heat." He passed in review the various methods of treatment of inoperable carcinoma now in vogue and pointed out that heat was the oldest and most effective treatment. He further drew attention to the fact that the main object was to get rid of the gross mass, and referred to the different methods of applying heat with this object in view. After showing that all of these methods possessed great drawbacks, he suggested a practical system of applying heat in otherwise inoperable cancer of the uterus which had none of the objections which could be urged against the other methods. The required apparatus was not only easily portable, but also inexpensive. He referred to the development of heat through a most efficient electric heating iron which could be perfectly regulated by means of a rheostat when applied to the involved tissue. With this electric heating iron and the vaginal dilator a maximum penetration and dissemination of heat was obtained in the involved structures. More than this, the low degree of heat, which his experiments showed to be more effective than intense heat, could be maintained accurately. This low degree of heat did not burn up the cancerous mass, but merely made it so hot that the hand of the surgeon, encased in a medium weight rubber glove, could not hold it. When this degree of heat was reached and maintained for from 10 to 20 minutes, the cancer cells were absolutely killed, while the normal tissue cells were not injured. The important thing was not to convert the pathology into charcoal. The charcoal or carbon thus formed inhibited the further dissemination of heat not only through the cancer mass but beyond. More than this, when the pathology was converted into charcoal, drainage was prevented for a number of days. This permitted of the absorption of a larger quantity of broken-down cancer cells than the average of these patients could tolerate, and many of them died as a result of this mistaken method of applying heat. Carbonization was produced in a few minutes by a cautery heated to a bright cherry color. Carbon inhibited the dissemination of heat. To overcome this still greater degrees of heat were required, which were extremly difficult to control, endangering the rectum, the bladder and the ureters. The heating iron, when used through the water cooled speculum, should not be hot enough to scorch a pledget of white cotton, if laid on the heating iron even for half an hour. Percy's experimental work and the operation itself demonstrated that when this "cold iron" was applied to the affected tissues, not only was there much less de-

struction of normal cells, but a far greater penetration of heat, sufficient to kill carcinoma. He believed that a large number of cases, if not practically hopeless when first presenting themselves for treatment, would give, treated by this method, approximately 50 per cent. remaining free from recurrence over five years.

Dr. Thomas Wilson, Professor of Midwifery and Diseases of Women in the University of Birmingham, read a paper on the "Results of Radical Operative Treatment of Cancer of the Uterus." In this paper the author laid especial stress on the difficulties of estimating justly the results of any curative method of treatment of cancer. He pointed out that cancer did not grow with equal steps, but now halted, again receded, and anon made rapid and tumultuous progress. When cancer began in the uterus one patient had recognizable symptoms at the very beginning, while another was conscious of nothing unusual until the disease was already far advanced. All things tended to show that the actual living virus of cancer, when at length it was discovered, would be found to pass through varying phases of growth and activity, now active and virulent, now sluggish or stationary. On the other hand, marked differences existed in individual hosts as well as in the various organs and tissues of the body.

Professor Wilson pointed out that in Great Britain, as, generally speaking, in America, gynecological work was spread over a large number of clinics of small or moderate size, and the opportunities afforded to the individual operator were comparatively limited. In testing and establishing a new operation, such as the extended abdominal hysterectomy for uterine cancer, this arrangement had many disadvantages when compared with the large clinics and extensive opportunities that were found on the European Continent. To this more than to any other cause was probably due the fact that these operations had been practised extensively and successfully in Vienna and Germany far in advance of the work that had been done here.

Dr. T. W. Eden, London, in discussing the papers read, commented on the fact that in these separate lines of treatment had been advocated for the same disease. He was inclined to reject the views of Dr. Percy, but if he could prove his claims by statistics, then in years to come everyone would do him honor. Dr. Eden was not in favor of radium in the treatment of cancer, and pointed out the discrepancy of the conclusions of Professor Bumm and Professor Krönig. He was of the opinion that the best promise of improvement was seen in *x*-rays combined with operation; one method alone should not be relied on, but combinations of methods adopted.

Dr. W. E. Miles, London, had never treated cancer of the uterus with *x*-rays or radium, and so would only consider surgical treatment. He insisted if a radical operation was to be performed on the necessity for removing not only the organ in which the primary growth originated but also the tissue through which spread would take place if the disease were unchecked. Mr. Miles emphasized the point that the crux of the cancer problem was early diagnosis.

Dr. Joseph C. Bloodgood, of Baltimore, remarked that the preceding papers truthfully revealed the results of operations for fully developed cancer diagnosed clinically. But surgeons had been too much taken up with the details of technique of extensive operations and thus they had not given sufficient consideration to the beginnings of cancer. He pointed out that in the great majority of cases cancer gave warnings to those in whom it was developing, and therefore any campaign of education in the beginnings of cancer was justifiable, no matter what the cost. At the stage in which cancer ought to be treated the mortality in skilled was so small as to be practically negligible. The early preventive treatment of cancer was all important, as it never began in a healthy spot.

The last evening session of the Congress, held in the Hotel Cecil on July 31, was mainly devoted to a discussion on intestinal stasis. As usual the hall was crowded with an audience eager to learn the views of some prominent British authorities on this much-vexed question. The speeches delivered on the subject were interesting and the majority of those who debated the matter appeared to be in favor of less radical methods than those advocated by Sir Arbuthnot Lane for the cure or relief of intestinal stasis.

Before the symposium on intestinal stasis commenced, Dr. W. L. Rodman, Philadelphia, opened a discussion on carcinoma of the breast. He dwelt chiefly upon the difficulty of diagnosing correctly between chronic fibrous and glandular hyperplasia, the result of abnormal involution of the breast, and cancer. He pointed out that the former condition was very common, especially about the menopause, and since the age of occurrence was so similar it was important to differentiate the two lesions. Chronic fibrous hyperplasia was frequently bilateral, whereas only 2 per cent. of breast cancers were bilateral. Early cancer was not painful, whereas abnormal involution was always painful. The pain was at its height immediately before each menstrual period, and enlarged superficial veins were then seen over the breast. Such veins were also seen in sarcoma, but not in carcinoma. Twenty per cent. of cancer of the breast occurred between twenty and forty years of age, and cancer, unlike benign neoplasms, soon became fixed by infiltration. If there were atrophy of the superficial fascia, however, small, or dimpling of the skin, however slight, the probability was that carcinoma was present unless chronic mastitis had previously existed. Comparison of the two breasts was of great importance in diagnosis, but retraction of the nipple had been given too much attention. In cancer the nipple was retracted, infiltrated, fixed and immobile, while in benign growths there was mobility and no fixation of the nipple. Rodman remarked that the differentiation of benign from malignant cysts was even more difficult than in the case of solid tumors, and he stated that although the expert might be able with fair certainty to tell the benign from the malignant growth by inspection, the less experienced could not do so; only froen sections examined at the time of operation would save the operator from mistakes. According to his experience the chance of making a mistake in the examination of a frozen fresh section was actually less than in that of fixed tissues.

Mr. W. Sampson Handley, London, said that cancer of the breast was not always a fixed tumor, nor did the skin always dimple over it. He agreed with Dr. Rodman with regard to the importance of frozen sections, but pointed out that pathologists as good as those with whom Dr. Rodman worked were rare. Mr. Handley's researches had convinced him that permeation was the true method of the growth and dissemination of cancer of the breast. The reason why permeation so long escaped observation was that it was at first a fugitive process.

While Dr. Rodman was speaking some disturbance was caused by a militant suffragette who insisted upon attempting to address the meeting. For about ten minutes she persisted in her attempt, but her voice was completely drowned by the shouts of those present. Eventually this disturber of the peace was removed forcibly by a commissionaire.

The symposium on intestinal stasis was opened by Sir Berkeley Moynihan, of Leeds. He first dealt with the membranes, veils or webs frequently found in the intestinal canal and admitted that their frequent presence was beyond cavil. He pointed out that the question of the origin or bearing of these bands could be disputed. Most of these he confidently believed to be of congenital origin. But the bands found at the hepatic and splenic flexures of the colon were seldom congenital. He agreed with Sir Arbuthnot Lane as to their origin. Yet he was disposed to doubt if these bands were responsible for intestinal delay and obstruction, for the gut was generally not hypertrophied as it should be if some obstruction existed. Delay undoubtedly occurred in the typical case of intestinal intoxication, not from obstruction by the bands, but from incapacity of the enfeebled intestine to empty itself. Moynihan was not in favor of radical operations, but was of the opinion that if surgical treatment was to be adopted it was wiser not to do a short-circuiting operation, but to take out the lower end of the ileum, the cecum and the ascending colon. As to the relations of intestinal stasis to gastric and duodenal ulcer and cholelithiasis, he believed that the cause lay more often in the appendix and not in intestinal stasis. Therefore, when surgical treatment was directed to these diseases the surgeon was exceeding his duty towards his patient if he dealt with anything beyond the demonstrable lesions of the case. Moynihan had seen cases of rheumatoid arthritis improved beyond the wildest expectation by operative abdominal measures. But it had to be remembered that drainage of an infected gall bladder or removal of a diseased appendix would cure some cases of this disease, and it had also to be borne in mind that most of these cases were not benefited by operative measures intended to prevent intestinal stasis. The same held good of tuberculous joints. Some of the worst kinds of such cases showed marvelous improvement after the whole of the surgical assault had been devoted to the intestinal canal. The casual relation was worthy of a wider trial and investigation, but more than that could not yet be said. Almost all the diseases that affected patients submitted to surgery, as well as many of those which were still for the present in charge of physicians, were regarded as amenable to surgery directed to the intestines. Moynihan accordingly felt that in existing circumstances he was very strongly disinclined to accept the evidence so far put forward in support of these views, but was eager to examine all new evidence bearing on the subject.

Sir Bertrand Dawson, London, said that the term "intestinal stasis" was being used in two different senses. One signified the actual delay in the passage of the intestinal contents; the other indicated the clinical picture of the results of such stasis. The employment of bismuth meals showed that many persons had delayed ileal effluent without suffering from any symptoms attributable to it. The large intestines played the principal part in the production of the symptoms of intestinal stasis; and the best results from coleotomy were seen when the large bowel was definitely diseased. It was important to put aside any bias against the colon, and not to get into the habit of regarding it as a useless organ which was just as well removed as left. The indications must be definite before the operation was advised. Apart from the mortality of colectomy, which was not negligible, it was often followed by frequent actions of the bowels at irregular intervals. The intestines were also easily affected after colectomy by changes of temperature and by fatigue. The successes of the operation were brilliant, but the failures were almost as striking. This was not in itself a condemnation of the operation, but merely constituted a plea for critical selection of cases, for the failures were not due to any faults of technic. If an appendix were removed, but the symptoms were not cured, at least no harm had been done to the patient. A gastroenterostomy which was unsuccessful could be undone, but a mistaken colectomy could never be undone, while a further reason for careful selection of cases was the fact that we did not know yet the full effects of colectomy on the future nutrition of the patient.

Dr. I. C. Bloodgood, of Baltimore, urged for the collection of more facts in the consideration of this subject. In how many cases, for instance, in which the appendix had been removed had there been failure to cure the patient's symptoms? In how many cases of gall-bladder disease, acute or chronic, with or without gall stones, was there a failure to cure symptoms by drainage of the gall bladder, removal of the stones or by removal of the gall bladder? In the past 25 years 700 such cases had been treated in the Johns Hopkins Hospital, and so far only three of them had returned with symptoms referable to the colon. For the purpose of anaylzing their cases at the Johns Hopkins Hospital the cases of colon disease were divided into five groups. In one of these groups, in which clinically the symptoms had been those of intestinal stasis, the patients had been relieved by the proper treatment of naso-pharyngeal and Simes affections. In the second group abdominal operations had been performed. In the Johns Hopkins Hospital gastroenterostomy was an operation which was not done if it could be avoided, but when it had been done the results had been uniformly good. The third group included those in whom adhesions had been found, embryonic or acquired. The results of operations for division of the adhesions, though good, had not been so good as those in similar cases from operations of a different type. The fourth group included the terminal cases now being discussed. Dr. Bloodgood concluded by saying that he could not convince himself that side tracking was an operation of choice, though it might be one of necessity.

Sir Arbuthnot Lane spoke very briefly. He merely remarked that he had nothing whatever to add to what he had said over and over again upon intestinal stasis. If his views were correct they must eventually prevail; if not, they would just as certainly perish. He was content to leave his audience to judge the result.

Injury of the Deep Branch of the Ulnar Nerve.—C. Woodward reports the case of boy aged 15 years who fell on a spike and wounded his left wrist and palm. The wound was infected and healing occupied some weeks. There was paralysis of the interossei, ulnar lumbricales, and adductors of the thumb. Owing to the absence of sensory changes this lesion was prone to be overlooked at the time of the injury.—*Proceedings of the Royal Society of Medicine.*

1. Therapeutic Artificial Pneumothorax as Associate Treatment in Pulmonary Tuberculosis.—J. A. Lyon states that therapeutic artificial pneumothorax gives the best results when administered to those suffering from unilateral pulmonary tuberculosis free from adhesions. That its application should be confined to this class of patients is by no means true, and if it were its usefulness would be extremely limited. Bilateral cases in which the active disease on the untreated side is limited to the apex, will in many instances show satisfactory improvement after being subjected to this treatment. When the treatment is resorted to when the active disease has extended beyond this point on the untreated side, the results will frequently be poor. The replacing of tuberculous pleural effusion with sterile nitrogen gas prevents, the formation of pleural adhesions and prevents the reaccumulation of the fluid. It is the author's belief that artificial pneumothorax is applicable to a very limited number of advanced cases of pulmonary tuberculosis, and that the best results follow its careful administration in that class of incipient and moderately advanced patients who fail, after a reasonable length of time, to respond to the older and better known forms of treatment.

2. The Function of a Dispensary.—M. M. Davis, Jr., states that dispensaries and out-patient departments, as one knows them today, have developed under the joint stimulus of two forces: the charitable impulse to relieve the sick poor, and the medical impulse to secure clinical material for hospital study or for teaching purposes. The dispensary has thus been either a medical "soup-kitchen" or a medical feeder or both. As a medical "soup-kitchen" the dispensary has not been taken very seriously by the lay public. As a medical feeder, it has not been recognized by physicians as possessing distinct functions of its own. Both as a medical and as a charitable institution it has been overshadowed by its rich relation, the hospital. Though the hospital beds treat fewer patients than the dispensary clinics, in the wards appear the crises and climaxes of disease which are usually more dramatic, and apparently more important. Certain advances in medical science, together with the rapidly growing interest in public health work, raise the question as to whether the dispensary or out-patient department has any distinct functions of its own, and whether, if so, dispensaries are at present so organized as to fulfill these functions properly. The development of modern medicine has created specialists and the best medical work can only be done as the team-work of specialists. The work of specialists demands such elaborate equipment, and their team-work requires so much time, that it is impracticable on a basis of private practice except for the wealthy. Dispensary organization as now developed is applicable not only to help the poor, but to provide medical service for those who can pay reasonable fees. In no other way can the best medical service be made available to the people as a whole. The organization of self-supporting dispensaries, on a business though not a merely commercial basis, is thus called for in the near future. The dispensary has a special medical field of its own. In this field fall a large group of important diseases, and many other diseases in their early stages. The dispensary is also peculiarly adapted for preventive work. The dispensary and the hospital are interdependent; the hospital is the center for advancing medical knowledge and medical education in its community; the dispensary is a center in which medical knowledge is to be applied for the benefit of the largest proportion of the population. The dispensary feeds hospital wards, follows up discharged patients (thus promoting hospital efficiency), and forestalls the need of hospital service by detecting and curing illness before it requires bed care (thus promoting economy of hospital service). Criticism of inefficient dispensary work is wholesome. The number of dispensaries in the United States has increased from about 100 in 1900 to over 700 in 1914. Standards of service must now catch up with magnitude of service.

3. Municipal Criminal Courts of Boston.—V. V. Anderson has made an analysis of one hundred cases, in order to illustrate the varying types of individuals that are to be met with in the ordinary daily run of the municipal criminal courts of Boston, as well as the great importance of handling each according to the particular problem he or she presents. In each instance there was obtained a life history of the individual; a record of his present physical and mental condition; and a fairly accurate knowledge of his mental capacity, of his mental traits, and of the preponderating opportunities and interests as shown by study of his mental content. This information was laid before the judge with suggestions as to the prognosis and treatment. The one hundred cases appear on the court record under the following offences: 22 cases of larceny, 45 cases of drunkenness, 6 cases of assault and battery, 1 case of selling drugs, 10 offences against chastity, 2 cases of running away from home, 2 cases of vagrancy, 7 cases of non-support, 1 case of highway-robbery, 3 of threats, and 1 of obtaining goods under false pretenses. It was found that the 22 larceny cases contained 8 feeble-minded individuals, 2 cases of dementia præcox, 3 constitutional psychopaths, 4 subnormal individuals, 2 epileptics, 1 case of ataxia paraplegia and 2 normal individuals. Of the 45 individuals arrested for being drunk, the record showed that 11 of them were feeble-minded, 3 were suffering from dementia præcox, 1 was a case of alcoholic hallucinosis, 17 were constitutional psychopaths, 5 were subnormal in mentality, 5 were epileptics, 1 was a case of senile dementia, 1 was a case of hysteria, and 1 was normal. Of the six arrested for assault and battery, 3 were feeble-minded, 1 was a case of dementia præcox, 1 was a case of epilepsy, and 1 was normal. The one individual arrested for selling drugs was a paretic. Of the 10 individuals arrested for offences against chastity, 5 were feeble-minded, 3 were subnormal in mentality, 1 was epileptic, and 1 was normal. Of the two individuals arrested for running away from home, 1 was feeble-minded and 1 was subnormal. Of the two vagrants, 1 was feeble-minded and 1 was a constitutional psychopath. Of the seven cases of non-support, 1 was feeble-minded, 1 was suffering from dementia præcox, and 5 were constitutional psychopaths. The one individual arrested for highway robbery was, from the intellectual standpoint normal. Of the three cases of threats, 1 was suffering from dementia præcox, and 2 were constitutional psychopaths. Finally, the one individual arrested for "obtaining goods under false pretenses," was a constitutional psychopath, who had been on one of his periodic drunks for several weeks, was markedly disordered mentally.

4. **Diagnosis and Treatment of Early Pulmonary Tuberculosis.**—J. B. Hawes, 2d, states that there are two grave mistakes which any physician may make in the diagnosis of early pulmonary tuberculosis. The first and most important of these errors is putting off making a diagnosis until too late; the second consists in making a diagnosis on insufficient evidence. The chief factors which lead many doctors to delay making a positive diagnosis of incipient consumption and instituting treatment may be grouped as follows: (1) Waiting for a positive sputum. (2) Disregard of the fact that a hemorrhage from the mouth almost always means pulmonary tuberculosis. (3) Failure to note and give due weight to constitutional signs and symptoms. Such signs and symptoms may be: Fever and rapid pulse. Unexplained loss of weight. Loss of strength and energy. Undue fatigue and ease of tire. (4) Failure to take a careful history. (5) Unwillingness to make a definite diagnosis for fear of losing the patient or of making a mistake. (6) Being in too much of a hurry. The chief factors in causing errors on insufficient evidence are: (1) Failure to remember that in young adults particularly, extensive signs in the lungs without constitutional signs or symptoms are often not of tuberculous origin. (2) Disregard of the fact that in children processes due to either pneumonia or influenza may cause consolidation, produce symptoms, and run a course resembling a tuberculous process in every detail. (3) Ignorance or forgetfulness of the fact that exophthalmic goiter often closely resembles incipient phthisis. (4) Forgetting that pulmonary syphilis is not as rare as is commonly supposed. (5) Failure to bear in mind that it is perfectly possible for a person to lose weight and strength, become weak and anemic, and even develop a cough and run a fever without these being due to tuberculosis.

5. **Some Unusual Phases of Sigmoidoscopy.**—R. W. Jackson notes that occasionally there may be surprising consequences of sigmoidoscopy, sometimes harmful and sometimes beneficial. Not frequently the sigmoidoscope produces abrasions and irritations of the bowel which are unpleasant, but which are usually avoidable with careful handling of the instrument. As to the more serious consequences of sigmoidoscopy, Tuttle says: "It may be suggested that there is danger of rupturing a weakened and inflamed intestine by such distention, as a matter of fact it is never so great as to produce any such effect. Whenever the pressure assumes any force, the air will escape through the sphincter or the plug will slip out." There are cases of intestinal perforation from pneumatic endoscopy or from forcing the instrument through some ulcerated area.

1. **General Paresis.**—D. M. Kaplan states that serological phenomena can be subdivided into four classes: (1) those of irritation; (2) those significant of cord compression; (3) those of syphilis and (4) those of general paresis. The phenomena of irritation comprise the pleocytoses encountered in the course of a meningitis. This increase in the number of cells in the cerebrospinal fluid may be marked or only slight. The number of cells can be used as an index of the severity of the meningeal irritation. In cord compression pleocytosis may be obtained without the presence of a protein excess. To find a very marked protein excess without a pleocytosis must be considered, however, as paradoxical. This is exactly what happens in patients with spinal cord compression. As far as syphilis of the central nervous system is concerned a positive serum Wassermann is inconclusive in settling the etiology of a given neurological disorder. Where the reaction is positive in the spinal fluid, one cannot doubt the syphilitic nature of the nervous disease. Of all positive serum and, to a lesser extent, spinal fluid Wassermann reactions, those obtained in general paresis will remain positive for a much longer time after treatment than the positive reactions obtained in the other syphilogenous nervous diseases. A positive Wassermann reaction obtained in a paretic's serum and spinal fluid possesses distinguishing characteristics. This peculiarity is the property of all Wassermann reactions that belong to the "Wassermann fast" type. The "Wassermann fast" phenomenon, in general paresis, is the expression of a spirochetal location that is so favorable to the existence and propagation of the spirochete that the latter is in a position to furnish continually the substances that bring about a positive Wassermann reaction in the serum and very often in the spinal fluid. The most characteristic landmark of general paresis, however, is to be noted when the cerebrospinal fluid of such a patient is brought in contact with a properly prepared solution of colloidal gold. The manner in which colloidal gold is precipitated by the spinal fluid of a paretic, is not obtainable with other syphilogenous diseases of the central nervous system. So far as paresis is concerned, it occurs with greater regularity in this disease than all the reactions already concerned. The precipitation of colloidal gold in general paresis occurs in over 95 per cent. of cases and in only one instance out of 634 analyses was a reaction obtained which corresponded to the characteristic curve of general paresis in a case of multiple sclerosis. Eight other cases of multiple sclerosis gave a negative result.

2. **Digitalis in Chronic Diseases of the Heart.**—L. F. Bishop points out that fibrillation of the auricle and very serious valvular disease, constitute the most frequent conditions in persons who are benefited by the use of digitalis over periods of months and years without interruptions. In both conditions, when broken compensation has recurred on two or three occasions and has been restored by digitalis after days of anxious waiting for the desired effect, a condition of well being, without these dangerous attacks, can often be maintained by suitably regulated doses taken continuously. The third type of disease in which the continuous use of digitalis often is indicated, comprises the later stages, or, as the author often calls them, the "digitalis stage," of arteriosclerosis, when the high blood pressure has a tendency to be succeeded by a lower pressure that falls beneath the line of compensation. The important point is to anticipate the need of digitalis. Careful observation often reveals defective kidney action several days before other signs appear. Thus, it may be needed once a week, or once in two weeks. If there comes a time when the digitalis will not act, it is not due to the fact that the heart has become habituated to the drug, but because the heart is no longer able to respond to the remedy. There is no such thing as a digitalis habit. On the other hand, there are many persons whose lives depend on digitalis, for without it they would have enjoyed but a short lease of life. The

continuous use of small doses does not lessen the efficiency of larger doses if required. Sometimes it is best to stop the digitalis entirely for a week, and then begin with larger doses. Digitalis may finally produce a true strengthening of the heart, and its use can suddenly be withdrawn without any danger. Groedel summarizes the matter as follows: (1) In all cases of cardiac insufficiency, when larger doses (the administration of which has to be restricted to a short period) of digitalis produce only transitory results, the continuous administration of small doses of digitalis is indicated and is beneficial in most cases. (2) The patients do not become so used to the remedy that they could not do without it. (3) The remedy does not prove ineffective in consequence of patients getting into the habit of taking it. There are certain contraindications that should be borne in mind; for instance, if the secretion of urine apparently diminishes under digitalis, it is well to stop for a while, and allow this effect to subside. Later, even larger doses may lead to diuresis. Digitalis is not yet completely known, and the author hopes there may be a few discussions of this important matter of its use as a chronic treatment of chronic conditions.

3. **Conservation of Vision.**—F. Allport emphasizes several points connected with the annual, systematic examinations of school children's eyes by school teachers: The examinations are simple and require no medical education. Teachers are not expected to make diagnoses. A child can be easily examined in five minutes, and each teacher should examine the children attending her own room. The tests not only benefit the children by leading to the correction of their eye, ear, nose, and throat defects, but the correction of these defects benefits the teachers, because such corrections usually add materially to the intellectual and moral character of the children, thus rendering them much easier to teach, and more pliable to discipline. There is no objection to these examinations being made by doctors or school nurses. This, however, would cost large sums of money and boards of education and health are never allowed enough money for even ordinary purposes. The author recommends the distribution in all schools of crisply and plainly written leaflets concerning the care of the eye, ear, nose, and throat.

4. **Surgical Treatment of Infantile Paralysis.**—J. W. Moore notes that the treatment of infantile paralysis may be divided as follows: (1) Acute febrile stage or that of onset. Within a few hours or a few days after the onset the paralysis appears. The paralysis may extend slowly or the extreme limit may be reached at once. Thus the duration of this stage may be from a few hours to a week. (2) Stationary period: In this stage the constitutional symptoms cease but the paralysis remains. Duration a week to a month. (3) Stage of spontaneous repair. Some hold that this stage ends within six months after the constitutional symptoms cease, but it is the working principle of this department to base the ending of this period at two years. Here the muscles or parts of muscles that suffer paralysis from secondary congestion and exudation about the local myelitis, recover their power, in whole or in part, while those muscles that get their nerve supply from degenerated nerve cells waste away. During this stage, then, contractures and distortions appear in the paralyzed limb. (4) Stage of residual paralysis: This stage has its beginning where the stage of spontaneous repair has its ending—namely, in two years after the initial onset. Treatment of the first stage is essentially medical. Treatment of the second and third stages implies massage, electricity, and support. Massage and electricity, should never be neglected. The routine use of galvanism, so long as it will induce contraction of the paralyzed muscles, is essential; support to the weakened muscles continuously by light braces, easily removable for daily massage and active and passive movements, is of the utmost importance. Should the contractures become so powerful that braces or apparatus will no longer prevent deformities, then conservative measures, such as tendon lengthening, etc., are advisable. There is nothing more distressing than when the attending physician neglects measures of support. The fourth stage or the stage of residual palsy, is the period of radical operation. One is confronted with two conditions: (1) Deformities; (2) loss of muscular power. If the treatment of the stage of spontaneous repair has been neglected, and the patient comes to the surgeon with contracture of the unopposed muscles, conservative measures must be carried out to correct the existing deformity, in the form of manipulation, forcible stretching, tenotomies, tendon lengthening, etc., and the limb must be retained in overcorrected position in plaster of Paris, before radical operation is to be undertaken. On the other hand, if the paralyzed patient has been properly and successfully treated through the stage of spontaneous repair without existence of notable deformity, here the immediate radical operation offers the best prognosis. Radical operation consists in utilizing the muscular power which remains unparalyzed, that is, tendon or muscle transplantation; or in extensively paralyzed conditions, where the joints are useless and flail-like, arthrodesis is desirable, especially in the subastragalar joint. However, in paralytic luxations of the shoulder or hip joint, muscle transplantation or reefing of the capsule gives excellent results. In tendon transplantation there are two methods to be considered, the one advocated by Vulpius, of Heidelberg, and the other by Lange, of Munich. The method of Vulpius consists in suturing the healthy tendon to the tendon or muscle which it is intended to strengthen. The objectionable feature of this procedure is that the paralyzed tendons stretch and the exertion is not likely to last, particularly where considerable strain is to be thrown on it, as in the leg muscles. The procedure has been abandoned by most surgeons. Lange's method consists in suturing the healthy tendon into the periosteum near the insertion of the weak muscle that is to be strengthened. When the joint is flail-like, and no muscular power remains, tendon transplantation is useless, and some method of joint fixation must be employed. A method of screw fixation of the ankle joint has recently been advocated by Magruder. He asserts that it is an effective substitute for arthrodesis, in that it is less destructive to tissue, quicker in results, much surer and much simpler.

5. **Is the Consumption Crusade Becoming a Burlesque?**—T. J. Mays believes that the campaign of education in the prevention of tuberculosis has been followed by widespread terror and demoralization. The ordinary feeling of pity and sympathy are chilled and calloused. A consumptive in a family is frequently neglected by the other members. Coughing on the street, in public conveyances, churches, and theaters is viewed with suspicion. Even the members of a family in which there is a sufferer from this disease are circumspectly avoided. The doors of hotels, of boarding houses, and even of health resorts are closed against them. The campaign of education in its present form is carried to extremes. It causes a revulsion in the minds of the people; some of its cruder elements, like the chamber of horrors, etc., should be eliminated, and one should proceed on less strenuous lines. The campaign of education has signally failed to make an

impression on the course of consumption; the imprisonment of all consumptives in closed institutions, is the last culmination of a most desperate movement, which, after causing irreparable injury, will end in greater failure than any of its preceding steps. The medicopolitical reformers of the present day are nursing a monster in the form of the goddess of health, which has already riveted the yoke of oppression on their consumptive countrymen, and this on evidence so frail that it would not be tolerated by any impartial tribunal.

1. Medical Treatment of Chronic Intestinal Stasis.—W. A. Bastedo sums up the treatment of chronic intestinal stasis as follows: Regularity of defecation, measures to improve intraabdominal pressure, measures to increase peristaltic activity, and measures to increase the bulk and softness of the colon contents. In the average case attention to habits of life and to the amount and kind of food, and the administration of a softening agent or a very mild laxative will be effective in overcoming the stasis, and, therefore, the toxemia. In severe cases, the addition of an oil enema at night may work a marvelous change for the better. In these chronic cases the drastic cathartics should be omitted from use. If measures such as those spoken of, when carried out thoroughly, do not overcome the stasis and the toxemia, the question of surgery should be seriously considered.

2. International Standard for Testing Vision and Standardizing Other Visual Tests.—E. Jackson states that the cards of test-letters in common use are admirably adapted to the subjective determination of errors of refraction; but as a test for visual acuity they probably afford the poorest and most inexact standard on which any scientic observations are now based. As a scientific standard they possess two essential defects: (1) The different letters when made as uniform as possible are visible from very different distances. This makes them unsuitable for a scientific standard. (2) They can be readily committed to memory by all who are sufficiently familiar with them to make them a convenient test. This lessens their value as a practical test. There is a great advantage in the use of the incomplete square or the broken ring of the international test. If the card on which one or more of these tests are symmetrically placed is simply turned, it becomes impossible for the person tested to know, except by sight, in what direction the incomplete side is placed. By using a single broken ring or a symmetrical group of them printed on the center of a symmetrical card, the same card can be used for any number of repetitions of the test, without giving any hint of the correct answer, except by vision sufficient to recognize the figure.

5. White-Spot Disease.—G. M. MacKee and F. Wise conclude that white-spot disease is a special form or type of scleroderma which can be differentiated both clinically and histologically from other affections with white lesions. Lichen planus sclerosus and atrophicus or lichen albus, although giving rise to white lesions, has nothing in common with white-spot disease. The unclassified cases of white-spot disease, such as those of Westberg, Johnston and Sherwell and Hazen, belong to the scleroderma group and, therefore, are true examples of white-spot disease. The discrepancies in histological and clinical findings are due to the fact that the studies were made at different times with respect to the evolution of the disease.

9. The X-Rays in Therapeutics.—G. C. Johnston concludes that the *x*-rays are of distinct value in the treatment of a number of conditions. The results to be expected depend on the employment of a correct technique which implies the ability to prescribe correctly and administer the necessary dosage at the necessary time in each individual case. The Coolidge tube has placed in the hands of the profession an instrument capable of great good if carefully and intelligently employed. The value of radium as a therapeutic agent should be no longer disputed. The physician employing these various agents must be thoroughly familiar with the possibilities of present day surgery as well as expert in his own technique in order that his patient may obtain the benefit of everything that science has to offer. Physicians and the public must never forget that every case of malignancy remains for a certain length of time after its inception a curable disease by proper surgical procedure.

11. Appendicitis with Special Reference to Pelvic Complications.—By A. MacLaren. (See MEDICAL RECORD, June 27, 1914, page 1192.)

12. Appendicitis.—By J. E. Moore. (See MEDICAL RECORD, June 27, 1914, page 1193.)

13. Thrombosis and Embolism.—By A. McLean. (See MEDICAL RECORD, July 4, 1914, page 38.)

14. Standardization of Surgery.—By R. L. Dickinson. (See MEDICAL RECORD, July 4, 1914, page 38.)

15. Kraepelin's Conception of Paraphrenia.—M. J. Karpas states that it must be admitted that the splitting up of a large heterogeneous group into subgroups with the object of restricting the disease picture to definite clinical types implies a marked advance in objective psychiatric nosology. Hence the paraphrenia group is such a welcome addition to the modern classification of mental disorders. One must bear in mind in many instances a well defined line of demarcation between dementia præcox and paraphrenia is quite often very difficult to make; especially is this true of the confabulatory and fantastic forms. It is important to emphasize that in the psychopathology of dementia præcox, emotional and volitional deterioration and distortion of personality stand out quite prominently, but they are only objective landmarks to aid one in establishing such differentiations. Kraepelin lays little or no stress on the type of personality in paraphrenia or other forms of psychosis, which is so much emphasized in American psychiatry. Should it be possible to outline a characteristic type of personality and the underlying psychological mechanisms of a paraphrenic symptom complex our knowledge of this important group would be greatly enriched.

Insurance Medicine.

Association of Life Insurance Medical Directors.—The twenty-fifth annual meeting of this Association will be held in Hartford, Conn., on Wednesday and Thursday, October 7 and 8, in the Hunt Memorial Building. The first session will be called to order at 10 A.M. on Wednesday, October 7. Besides the general business which will be brought before the Association, the following papers will be read: "Decreased Mortality from Tuberculosis," president's address, by Edward K. Root, M.D., medical director, Ætna Life Insurance Company; "Heredity and Predisposition in Life Insurance," by Arthur B. Wright, M.D., medical director, Travelers' Insurance Company; "Analysis of 1,000 Ordinary Rejections, 1888-1903, of Applicants Holding Other Ordinary Insurance, Observed in 1914," by William Perry Watson, M.D., Consulting Medical Director, Prudential Insurance Company of America; "The Terms on Which Some Substandard Risks May Be Accepted," discussion introduced by T. F. McMahon, M.D., medical referee, Manufacturers' Life Insurance Company.

Inflammatory Rheumatism and Allied Disorders as Affecting Life Insurance Risks.—Dr. C. Nauman McCloud, Medical Director Minnesota Mutual Life Insurance Company, states that until very recently but little was known about the etiology of these affections. Inflammatory rheumatism is now regarded as one of the most special and definite diseases with which we have to deal, although there may be different types which the future will determine, just as there are different types of the pneumonococcic infection. In a brief review of the newer theories as to the etiology of inflammatory rheumatism we must correlate the close relationship of the tonsils to this disease. During the past twenty years investigators have endeavored to settle this problem and confusion has existed because the organisms did not altogether coincide, yet the recent work of Rosenow of Chicago seems adequately to adjust these differences. In 1892 Sahli discovered *Staphylococcus pyogenes aureus* in the synovial membrane of the joints and also in the pericardial exudate of a patient suffering from inflammatory rheumatism. Dana, in 1894, isolated a diplococcus from a case of chorea following rheumatism. In 1899 Wassermann, Westphal, and Malkoff reported a case of chorea following inflammatory rheumatism, which later died, in which was found a diplococcus in the tissues that appeared in cultures as a staphylococcus. More recently Poynton and Paine have been able to reproduce inflammatory rheumatism in rabbits by injecting them with blood of rheumatic patients and later were able to demonstrate the same diplococcus as found in the patient. They called this microorganism the *Diplococcus rheumaticus*. The experiments of Rosenow show that the same organisms may be changed by cultural methods so that they may demonstrate progressive phases of transmutation. This range extends from the streptococcus to a pneumococcus. He has produced at will, in the inoculated rabbit, suppurative arthritis, multiple proliferating arthritis, endocarditis, pericarditis and myocarditis, myositis of skeletal muscles, in various phases, and at another stage produced a typical pneumonia. These experiments probably clear up this difference in results from the varying types of streptococci described by the various investigators, and further develop the interesting fact that the same organism producing inflammatory rheumatism is found in the tonsils of rheumatic patients. While the presence of the *Diplococcus rheumaticus* in the tissues is essential in the production of this disease, there are predisposing causes of much practical importance, and among these are the following: Heredity.—Inflammatory rheumatism renders the patient liable to other attacks, and as a result a constitutional tendency is developed which may be transmitted to the offspring. Sex.—In childhood rheumatism is more frequent in females, and it is apt to be less acute but more obstinate due to some intrinsic peculiarity of female metabolism. The condition of the tonsils at this age is an important factor, as necrosed tonsils are too frequently associated with rheumatic conditions. Personal Hygiene.—Care of the throat, proper clothing to protect the body from sudden climatic changes is necessary. It has been definitely proved that the tonsils, teeth, and alveolar processes are a source of these infections. Billings and his co-workers have shown that the organism found in the abovementioned tissues and organs is the same as that found in the joints of an arthritic patient, and they have produced at will these same conditions in animals. Patients suffering from arthritis deformans have been relieved of their helplessness by proper dental attention and removal of the tonsils, which resulted in an arrest of the severe arthritis and muscular wasting. The specialized mortality investigation relating to rheumatism has shown that applicants who have had rheumatism have proved to be fair risks. While this seems to be contrary to clinical experience, it may be due to a somewhat loose application of the term rheumatism, as covering such conditions as lumbago, sacroiliac involvements, etc.

In insurance work, Dr. McCloud says, the examiner is chiefly concerned with the heart involvement in cases of inflammatory rheumatism. The medicoactuarial investigation will include a study of the mortality among persons who have suffered from acute articular rheumatism, the last attack being within five years, and excluding muscular rheumatism. It is to be hoped that a classification according to the date of the attack can be made, so that results may be obtained which will be more directly helpful to the medical director in rating cases with this history.—Medical Section. American Life Convention, March, 1914.

Mitral Stenosis and Life Insurance.—At a meeting of the British Life Assurance Medical Officers' Association held on November 5, 1913, Dr. F. de Haviland Hall pointed out that a much too optimistic view seemed to have been taken of the prospects of the applicants with circulatory disturbance, and the additions were consequently quite inadequate to the risk. The speaker adduced an instance going to show that this conclusion was correct. The applicant for insurance was 36 years of age, 5 feet 11 inches in height, and 182 pounds in weight. His father had died at the age of 52 of Bright's disease. His mother was alive at the age of 67, but she had suffered several times from rheumatic fever. The applicant was found to have a double mitral murmur and on exertion he suffered from dyspnea. He was taken with ten years' addition, the premium to be paid in ten payments. He died from heart disease after the second instalment had been paid.

Book Reviews.

A Synopsis of Surgery. By Ernest W. Hey Groves, M.S. M.D., B.Sc. (Lond.), F.R.C.S. (Eng.). Surgeon to the Bristol General Hospital; Consulting Surgeon to the Cossham Hospital; Lecturer on Surgery at Bristol University. Fourth Edition, Revised and Illustrated. Price, $3.25 net. New York: William Wood and Company, 1914.

This work is not designed to supplant or serve the purpose of a text-book, but rather is an epitome of the salient facts in surgical practice, and the author has accomplished his purpose most admirably. The essential features in the etiology, pathology, symptomatology, diagnosis and treatment are clearly brought out, though in as brief a manner as is compatible with conveying a lucid impression of the subject in question. It may well be called invaluable for quick reference, for purposes of review, and as an aid in the preparation for examinations.

In this edition the author modestly states that the most important new feature is the revision, and to some extent the rewriting, of the pathological and bacteriological sections by Dr. George Scott Williamson; but additional new matter has been incorporated covering recent theories of shock, intratracheal and other methods of anaesthesia, spinal-cord tumors and resection of spinal nerve roots, while the entire book has been carefully revised and brought into accord with the latest teachings in the realm of surgical practice. It is without question one of the best outlines of the practice of surgery in existence, and a valuable aid to the practising surgeon as well as to the student.

Surgery: Its Principles and Practice. For Students and Practitioners. By Astley Paston Cooper Ashhurst, A.B., M.D., F.A.C.S., Instructor in Surgery in the University of Pennsylvania; Associate Surgeon to the Episcopal Hospital and Assistant Surgeon to the Philadelphia Orthopedic Hospital and Infirmary for Nervous Diseases. Large octavo, 1141 pages, with 7 colored plates and 1032 illustrations in the text, mostly original. Price, cloth, $6.00 net. Philadelphia and New York: Lea & Febiger, 1914.

According to the publishers' announcement, this book "will be promptly recognized on its merits as the leading text for students, and the ideal guide for all those who have practical surgery to do." The reviewer regrets that he cannot concede this claim. In the preface of a recent book on another topic there occurred this statement: "I will go even further and say that a book that does contain useful information but information that is already contained in other books previously published, has no right to exist unless the author at least presents the matter from a new point of view, or classifies it in such a manner as to make its comprehension more easy, more assimilable. It is unfortunately only too true, however, that thousands of books are published annually which have absolutely no *raison d'être*. They present merely a rehash of some other book or a résumé of several." This book does not deserve quite so harsh a criticism as this; but there is a surfeit of such surgeries that have recently appeared or been revised and brought strictly up to date, so that there should be some compelling reason for a new author's appearance in the field—a reason which we confess we have failed to discover in the work itself.

While it is true that the author has drawn upon his own experience in the preparation of parts of the work, a very considerable portion falls in the category of compilations from other books and journal articles. It is also true that he has well summarized recent literature, and the entire book gives evidence of wide reading and the expenditure of an enormous amount of labor in collating material of this nature, but the proportion of original to borrowed material seems very unequal.

The most satisfactory sections are those covering injuries and diseases of the bones and joints, including fractures and dislocations, and those on the surgery of the chest and abdomen, particularly of the upper abdomen, where the influence of the author's association with Deaver in the preparation of a recent masterly work on this subject is manifest. The section on hernia also deserves special mention. There are, of course, many excellent features. The illustrations are almost uniformly good and to the point, while an unusually large percentage are original. The style is easy, the text is clear, and for the most part truly reflects the present conceptions of surgical principles and practice. However, it is better as an addition to one's surgical library than as a textbook in the usual sense of the word; for only too often one cannot be sure whether he will find an important subject treated *in extenso*, briefly, or not at all.

Renal Diagnosis in Medicine and Surgery: Being a Handbook of the Theory and Practice of Functional Testing of the Kidney. By Dr. Victor Blum, Tutor in Urology at the University of Vienna. English translation by Wilfred B. Christopherson. Price, $2.00 net. New York: William Wood & Company, 1914.

Only a comparatively few years ago the determination of the functional value of a kidney was based upon and limited to the interpretation of the clinical symptoms and the examination of the voided urine; that from a supposedly sound kidney thus being mixed with that from the diseased side. To obtain urine from the diseased side only various measures were adopted, among which may be mentioned compression of the ureter on the sound side by pressure through the abdominal wall, and the use of one of the various separators, that of Luys being the most practical in the average case. While seldom absolutely accurate and usually difficult in application, the separator furnished an approximate sample of the urine from each side and the usual physical, chemical, and micoscopical tests could then be applied to each specimen. The development of the catheter-cystoscope simplified the collection of urine from the individual kidney and attention was soon directed to the problem of determining the functional condition not only of the kidney as a whole, but of the different portions of the renal parenchyma, topical diagnosis. The methylene blue, indigo-carmine, phenolsulphonephthalein, sodium chloride and potassium iodide, and many other tests were gradually developed; so that at the present time the state of the kidneys may be fairly accurately determined before operation or during the course of medical treatment of renal disease. As Blum states, "The significance of the modern methods of examination is threefold: (1) In the diagnosis of renal competency and incompetency; (2) in the differential diagnosis of the various forms of nephritis; (3) in the diagnosis of 'harmless' albuminuria." Blum has certainly covered the ground, and has epitomized in this book about all that it is necessary for one to know as to the development, technique, and the practical application of all the functional tests that are in general use at the present time.

Bacteriology for Nurses. By Isabel McIsaac, R.N. Second edition, revised. Price, $1.25 net. New York: The Macmillan Company, 1914.

This book is the result of "an endeavor to bring the essentials of an enormous subject into a practical arrangement, which will serve to introduce young nurses to one of the most important phases of nursing, viz., the prevention of infection." The subject is taken up in a clear and acceptable fashion, though the distribution of space is somewhat puzzling, for more is devoted to a description of the bubonic plague than to any other disease with the exception of tuberculosis. The revision for the new edition could have been accomplished a little more thoroughly in some respects. For instance, the author in the section on syphilis quotes Colles' Law, which has been rather thoroughly discredited by the Wassermann reaction, and also says that cases of gonorrhea and syphilis "almost never recover." In the main, however, the book adequately fulfills its purpose.

Manuel Pratique de Diagnostic Bactériologique et de Technique Appliquée a la Détermination des Bactéries. Par R. Le Blaye et H. Guggenheim. Price, 8 fr. Paris: Vigot Frères, 1914.

This practical manual aims to be to the bacteriologist what the botanical manual is to the botanist, to furnish a quick and simple method for the identification of any microorganism. The first half of the book is devoted to a brief description of bacteriological technic and the preparation of media and the taking of cultures. The second half is wholly devoted to tables which present, in what is said to be an entirely new form, the entire field of pathogenic microorganisms. Thus in one table is collected all the bacteria which liquify gelatine and directions given which will enable one to differentiate between them. It is probable that when one became accustomed to use these tables that they could very quickly furnish any desired information. The chief objection is that an equal amount of time spent in the intensive study of the subject would give the student sufficient information so that the tables would not be necessary to him.

Society Reports.

AMERICAN PEDIATRIC SOCIETY.

Twenty-sixth Annual Meeting, Held in Stockbridge, Mass., May 26, 27, and 28, 1914.

THE PRESIDENT, DR. SAMUEL MCC. HAMILL OF PHILADELPHIA, IN THE CHAIR.

President's Address.—Dr. SAMUEL MCC. HAMILL, Philadelphia, Pa., made this address in which he first paid a tribute to the memory of Dr. Forchheimer, Dr. Rotch, and Dr. Putnam. He said that as friends they would miss them, but that they should miss much more their stimulating influence in this Society, and, above all, their contributions to the subject of pediatrics and the betterment of the world. As a text for his remarks he took a quotation from the first volume of the Transactions of this Society, quoted from Dr. Jacobi's first epistle to the Pediatricians, written in the year 1888 on the occasion of the first scientific meeting of the American Pediatric Society. It read: "Questions of public hygiene and medicine are both professional and social. Thus every physician is by destiny a 'political being' in the sense in which the ancients defined that term; viz., a citizen of the commonwealth, with many rights and great responsibilities." In that communication, after defining at length the close interdependence of pediatrics to general medicine, surgery, neurology and to all other branches of medicine, he emphasized the relationship of pediatrics to the most vital questions of public hygiene. The speaker quoted further from Dr. Jacobi's paper of twenty-six years ago which indicated in very definite terms what he thought to be the duty of this society and its individual members to the problems of the commonwealth. Though Dr. Jacobi had been the pioneer in pointing out this duty of the American Pediatric Society others had from time to time suggested that the American Pediatric Society, primarily founded to stimulate and encourage scientific work to the highest degree, should assume broader obligations and grapple with larger problems. In the light of the standing of this organization had they the right to refuse consideration of the vital problems of preventive medicine that were being unwisely and irrationally disposed of by men and women who were often swayed by sentiment and who were without the knowledge of medicine, upon which, in the final analysis, every problem relating to the child must rest. In answering this question affirmatively Dr. Hamill said he would not convey the impression that the American Pediatric Society should sacrifice one particle of its scientific endeavor along lines of laboratory and clinical research, but that it should add to its program scientific investigation along the lines of preventive medicine as it applied to the welfare of the child. The subjects of birth registration, the regulation of the midwife, the problems presented by the day nursery and the foundling institution, and the problems of school hygiene, all demanded their attention. Many of the private schools for boys and the great majority of girls' schools, as housed in our cities, were a menace to the public health. They were receiving neither advice nor supervision. The problems of the physician and the sociologist were inseparable. This, the speaker said, was well illustrated in the matter of the health aspects of the child labor problem. As Dr. Rotch had pointed out, the knowledge which the pediatrist alone could give would prevent the enactment of laws which were unwise and unjust both to the child and to his parents and employer. The health departments of some of our cities had made special provisions for the care of the city child by the creation of departments of child hygiene, and this society should do all in its power to stimulate the creation of such departments, rightly conducted, that the terrific morbidity and mortality amongst infants and children would be reduced. Much of the invalidism of the adult, mental and physical, much of the moral obliquity of the child and the adult, had as their foundation the neglect of the medical aspect of these sociological problems. Those in close touch with charitable, philanthropic, educational and social institutions in our cities, most of which were in part public health programs, and most of which were formulated and carried out without medical advice, understood the crying need of the assistance that such a society as this could render. There was no other which could fully replace it.

As to our method of procedure, the suggestion of Dr. Edsall that this society act as a center for the accumulation and dissemination of knowledge relating to these subjects was admirable. They could not treat all of the innumerable themes that were awaiting them at once, but these could be brought up one by one at the yearly meetings. Dr. Hamill therefore recommended that at the present meeting three committees of three members each be appointed—the first to study the present status of the child labor problem, and to present a critical and constructive report at the next annual meeting; the second to study the vulvo-vaginitis problem in its relationship to public health, its report to be submitted at the same meeting; and the third to be known as the Committee on Cooperation with the Children's Bureau of the United States Department of Labor.

The Use of Dahlia.—Dr. JOHN RUHRÄH of Baltimore read this paper, in which he gave a brief history of the observations on aniline dyes with reference to their antiseptic action, and reviewed the recent observations of Simon, May, and others, showing the germicidal properties of certain of the basic aniline dyes. He stated that two years ago in searching for an efficient local application for streptococcus infections of the throat Dr. Charles Simon had suggested dahlia. He started with a local application of a weak solution and soon found that the saturated solution, that is, about a four per cent. solution, could be applied to the mucous membranes of the throat or any other part of the body without producing pain or subsequent irritation. The drug seemed to penetrate only a short distance and for the deeper affections had no value, but for superficial involvements of the mucous membranes, whether due to the streptococcus or other organism, the effect was quite striking. In some instances there was but little effect while in others there was marked lessening of the intensity of the inflammation and coincidently a lessening of the constitutional symptoms. Dahlia had the advantage over other applications in that it was not painful, did not produce irritation, and was markedly antiseptic. The drug also had a stimulating effect on healing. It had been used with remarkable effect on vaccinations that were slow in healing and upon other abraded surfaces, particularly those which were infected. Others had used it with success in chronic eczema, herpes, tinea, tonsurans, furunculosis, and erysipelas.

Dr. ABRAHAM JACOBI of New York said that he had published a paper some eight years ago in the Journal of the American Medical Association on the effect of methylene blue in cases of cancer in which he had called attention to the advantages of this agent in chronic cancer by giving it, not subcutaneously, but internally. The paper had been conscientiously overlooked, as many good things were. He had used methyl blue for twenty-three years and was still satisfied with it.

The Diagnosis of Whooping Cough by the Complement Deviation Test.—Dr. ALFRED FRIEDLANDER of Cincinnati presented this communication. He stated that they had succeeded in making the diagnosis of whooping cough in all stages by means of the complement deviation test. After describing his technique, which had the advantage of requiring but a very small amount of blood, he reviewed the series of cases which had been subjected to this test and showed that in eighteen cases of whooping cough there were 100 per cent. of positive reactions; in eight normal children there was 100 per cent. of negative reactions; in three cases in the catarrhal stage, two gave positive and one a negative reaction; in a case not whooping cough, but in which the course was otherwise typical, there was a positive reaction. In no case had he had a positive reaction when the patient had not either a pertussis infection or a history of pertussis within four years. It was a matter of record that the success of vaccine therapy in whooping cough depended in a large measure on the time of its application. If it were possible to diagnose whooping cough in the catarrhal stage surely and definitely its rapid cure seemed assured.

Dr. ROWLAND G. FREEMAN of New York said that this work seemed very promising, but the general impression seemed to be that they were still uncertain as to whether the specific organism of whooping cough had really been found. In one laboratory in New York they had been experimenting all winter but without results.

Dr. CHARLES GILMORE KERLEY of New York said he had had the opportunity of discussing this subject with Dr. Freeman of London, Eng., who had treated 1134

cases of whooping cough with vaccines. He felt rather vague as to the results, but thought that the vaccines probably did some good; used in conjunction with the pneumococcus vaccine he thought they gave good results.

Dr. Samuel S. Adams of Washington, D. C., thought that the value of this test hinged on the early diagnosis. Was there a history in these cases? A history of disturbed sleep was a symptom which usually appeared long before other symptoms. It seemed that if this test was to be of value we must get the child before there was a distinct history.

Dr. L. Emmett Holt of New York called attention to the close resemblance in some cases between influenza and whooping cough, which made it very desirable to differentiate them bacteriologically. They had had a great deal of influenza in the Babies' Hospital during the past winter and took cultures from all the inmates of the institution, with the result that the influenza bacillus was found in the sputum of a very large proportion of the cultures. In some cases the symptoms were quite typical of whooping cough. This close resemblance between the two diseases in some cases might account for the negative result in the series reported.

Dr. Alfred Friedlander of Cincinnati said that in reference to the question as to how long the children had been coughing, the periods had varied from three to ten days. When a child showed any definite history of cough the test was made and the normals had some cough. In some the diagnosis of influenza was made in accordance with Dr. Holt's statement. One could no longer question the specificity of the Bordet-Gengou bacillus. They had been using it in three stains and got a definite deviation of the complement in each. So far as the value of the vaccines was concerned there was room for doubt; from relatively small doses one got no results.

Endocarditis in Children.—Dr. Floyd M. Crandall of New York presented this communication, which was based on the study of the case histories of private patients, some of whom had been followed for many years. His general conclusion was that cardiac disease in private practice ran a considerably more favorable course than in hospital and dispensary practice. Four symptoms were particularly suggestive of myocarditis; namely, irregular heart action, syncope, cyanosis and precardial distress. In the later stages the occurrence of cyanosis and edema was of more grave significance in children than in adults. It was usually impossible to determine the condition of the heart muscle in a young child except during sleep. If anemia was a marked symptom the prognosis was not so gloomy, as relief of the anemia might mitigate the heart symptoms. A point of great interest was the occasional rapidity of the development of the physical signs of endocarditis. It was a common statement that the severity of the case was not in proportion to the amount of sound heard on auscultation; this statement was not wholly true. It was difficult to believe that a loud rasping murmur was not more serious than a soft blowing one. The physician who ignored the gravity of a cardiac murmur and lightly said the child would grow out of it was taking a criminal risk. The earlier the endocarditis occurred the better the prognosis because of the more perfect adaptation of the child to the heart and the heart to the child. An aortic lesion was a very dangerous thing in a child, but fortunately was a rare occurrence. The evil effects of anemia on a child with cardiac disease could scarcely be overestimated, as it was a contributing factor to weakness and fatty degeneration of the heart muscle. The evidences of infection through the tonsils in acute rheumatism were strong, and for this reason in the rheumatic child it was highly important that enlarged tonsils should be removed. The effect of endocarditis on the growth and development of the child were of particular interest, and it seemed that a constitutional tendency and rheumatic involvement were often more important factors in the development of the child than the heart lesion. The treatment of endocarditis divided itself into the treatment of acute and of the chronic conditions. Six weeks was the shortest time that any endocardial case might be allowed to leave the bed. Rapidity and irregularity of the heart on getting up were indications for a longer stay in bed. The time of getting up was largely a matter of judgment in the individual case. The maintenance of a restrictive treatment too long and too rigidly after the preliminary stage was a mistake, and might defeat its own object. A period of daily rest was of great importance to the cardiac child. In the management of this condition arbitrary rules might do more harm than good. In few other conditions was it more essential that we study the case and treat the patient rather than the disease.

Dr. Henry Dwight Chapin of New York called attention to the tendency of these cases to acute dilatation under great stress. In line with the address of the president, the physician had a duty to the public in pointing out the danger of the too strenuous athletics encouraged by our schools and colleges. These matters were left too much to physical directors, who were not alive to the dangers.

Dr. Henry I. Bowditch of Boston said he wished to emphasize the point just brought out by Dr. Chapin. The child with a damaged heart did not have a fair chance in life and needed the closest observation. A committee to take up this subject to which Dr. Chapin had referred would be productive of good results. As one observed more closely he would see that family history played an important part in these cardiac cases. There were frequently other cases of endocarditis in the family and it would be interesting also to note their association with streptococcic infection of the tonsils.

Dr. Fritz B. Talbot of Boston cited a case of endocarditis which had just come to his attention in which the sister had had rheumatism and endocarditis three weeks before; if these cases were studied more closely it would often be found that there was a history of other cases in the family. They had been conducting a heart hospital with very good results and were also trying to see what social workers could do in the way of keeping these patients in bed at their homes. They could not say as yet which was better, the hospital or the home treatment.

Dr. J. D. Crozer Griffith of Philadelphia believed that it was possible, where there was a great degree of debility, to keep the patient in bed too long. These patients might be divided into three classes: A small class where there was absolute failure of compensation; a larger class which responded well to treatment and in which recovery usually followed, and a class in which there was a tendency to an independent anemia not yielding readily to treatment. Some of these latter cases in spite of all treatment still remained discouraging.

Dr. A. D. Blackader of Montreal, Canada, said that, in reference to the effect of endocarditis on the development of the child, it had been pointed out that growth was dependent on wide arteries and a low blood pressure. A slight endocarditis by lowering the blood pressure and favoring wider arteries favored an increase in growth and these children might be found a little taller than others in the same family. When the temperatures had become normal small doses of potassium iodide given over a period of three, four, or five weeks was productive of benefit. Its effect on acidosis was well known and it was believed to have some effect on the viscosity of the blood. In mild lesions confined to the mitral valve, excepting for the more strenuous exercises, children should be allowed to develop the heart at the time that the remainder of the body was developing.

Dr. Henry L. Coit of Newark asked the essayist when he said that the child might get up when the pulse was 100 or less whether he meant 100 when recumbent or 100 when standing.

Dr. Isaac A. Abt of Chicago, Ill., called attention to the statement that aortic lesions were rare in childhood; in his personal experience he had not found them as rare as had been supposed and he was seeing an increasing number of cases. Occasionally in children with murmurs there might be only slight temporary dilatation after exercise, perhaps lasting for a period of days. What should one do in regard to exercise in these cases?

Dr. Rowland G. Freeman of New York said that no one had spoken of the value of the *x*-ray as a guide in the control of these cases of endocarditis. Cases showing an enlargement should be subjected to the *x*-ray when they show an improvement of symptoms. In a case coming under his observation in which the symptoms showed an improvement an *x*-ray picture showed greater enlargement than when the first picture was taken.

Dr. D. J. Milton Miller of Atlantic City called attention to certain adventitious murmurs not due to endocarditis which were exceedingly difficult to diagnose.

These cases were frequently permitted to go without treatment and sometimes disastrously. In cases of endocarditis in children small doses of morphine were valuable, especially when there was nervousness.

Dr. PERCIVAL EATON of Pittsburgh, Pa., suggested the longer administration of iron in the cases complicated with anemia. These children were sometimes kept in bed too long; one was apt to forget how much could be done by beginning with a very little exercise and very gradually increasing it.

Dr. HENRY I. BOWDITCH of Boston related a family history illustrating the hereditary predisposition to endocarditis and indicating an association to infection of the tonsils and expressed the conviction that this hereditary factor had something to do with the production of the endocarditis in some cases at least.

Dr. FRANK S. CHURCHILL of Chicago, Ill., said it would be interesting to know what the blood pressure was in these cases and whether it was different in the functional and the organic murmurs; whether it was less when the children were lying down than when sitting, and less when sitting than when standing. One could counteract the effects of too long rest in bed by passive exercises. The question of allowing the child up when the pulse was 100 depended on the age of the child and the blood pressure.

Dr. L. E. LA FÉTRA of New York thought that possibly the family tendency to endocarditis might be explained by the predisposition of the lymphoid tissue to infection being handed down from one generation to another. The blood pressure, together with the pulse rate, could be used to determine when the patient might be allowed out of bed. Sometimes the heart might be a little rapid for a few days after getting up, but after a short time it got its second wind, so to speak, and then went along all right.

Dr. HERBERT B. WILCOX of New York said that the anemia in these cases was amenable to treatment. One should get these children with endocarditis complicated by anemia into the country. They had tried this experiment last summer and most of the children returned permanently improved. This seemed to indicate why better results were reported in the treatment of cases in the families of the well-to-do than in those of the poor.

Dr. FLOYD M. CRANDALL of New York said that some of these patients if kept in bed too long developed hospitalism. It was well not to center the mind of the child too much on the heart condition. In connection with the relation of the family history of rheumatism to endocarditis, a family had come under his observation in which there were seventeen cousins and every one of them had either chorea, endocarditis, or rheumatism.

Treatment of Sibilant Bronchitis.—Dr. B. K. RACHFORD of Cincinnati read this paper, in which he expressed the belief that the symptom groups commonly described in the literature under the titles migraine, asthma, recurrent sibilant bronchitis, recurrent vomiting, recurrent coryza, and urticaria, as they occurred in children, were closely related food intoxications which could be successfully treated by very much the same dietetic and medicinal treatment. The case histories given showed the relationship of these conditions. During the attack sweets, fats, eggs, and raw fruits were to be avoided. Strawberries, rhubarb, tomatoes, salads, shellfish, tea, coffee, pastry, gravies, cream, cod liver oil, and alcohol were excluded from the diet. Saccharine might be used instead of sugar and skimmed milk was allowed. Eggs in every form, even in cooked foods, were eliminated, and oranges were especially to be avoided. The foods allowed were beef, mutton, fowl and fish in moderation, cereals, bread and all vegetables not proscribed above, cooked fruits, skimmed milk, and thick soups. About two months after the patient had recovered from the acute attack the above diet might be carefully modified by adding one egg a day and two weeks later milk containing four per cent. fat. A few weeks later a small quantity of sugar might be allowed, and at the end of five or six months the child might return to his original diet, with the exception that he must eat sparingly of sweets and must eat nothing between meals. If the symptom group returns on the addition of any article of food that particular food must be excluded from the diet. Exercise and fresh air were important. Alkalies in the form of bicarbonate of potassium, or citrate of potassium should be given in fair-sized doses three or four times each day. In younger children a teaspoonful of citrate of potassium might be distributed through the food each day. Tincture of belladonna, two to four minims three or four times a day, should be given for a short time. In the intervals the belladonna was discontinued, but the bicarbonate was continued for six or eight weeks.

Dr. PERCIVAL J. EATON of Pittsburgh said that last year he had seen ten cases similar to those just described and during the past winter he had seen from ninety to one hundred, and had felt that an element had come in which he had not seen before. He had met cases in nurslings and in children of all ages up to seven or eight years. These cases were new to him whether due to infection or to diet, though the latter was a new idea to him.

Dr. FRITZ B. TALBOT of Boston, Mass., said that Dr. Schloss had given the answer to the cause of these cases in his excellent paper on "Egg Anaphylaxis." In a case coming under his observation, in which there was egg anaphylaxis and asthma, when the immunity to egg was established the asthma disappeared. There might be anaphylaxis to other articles besides egg, and it seemed very probable that the condition just described was due to anaphylaxis. In one case one-sixty-fourth of a grain of egg given in capsule produced a reaction each time it was administered.

Dr. GODFREY R. PISEK of New York said that from what had been said Dr. Rachford's treatment was only palliative; the real treatment must reach the causative factor. It was not sufficient to stop the egg alone, but all foods containing egg as well. Some foods, especially the acid ones, brought out an intolerance for certain other foods, so that each case had to be studied from the individual standpoint.

Dr. HENRY L. COIT of Newark, N. J., called attention to the fact that many cases having an anaphylaxis for egg also had it for macaroni. In one case in which it was necessary to transfer a child from milk to a diet in which the carbohydrate would be in the form of starch and cereal, one teaspoonful of wheat jelly was given with a result that there was a rise in temperature, prostration, and vomiting. The mother was urged to try again and the same result followed the giving of the wheat jelly. The anaphylaxis in this case was overcome by vaccinating the child with a minute quantity of the wheat jelly.

Dr. WALTER LESTER CARR of New York said he wished to endorse Dr. Rachford's paper. Many of these children were unusually susceptible to infection, especially by influenza; they belonged to the so-called lithemic type, and one frequently found them with enlarged tonsils, deviated septum, etc. The children having this instability did better if treated as in enteritis, with ether, skimmed milk, or lactic acid, skimmed milk, and general dietetic regulation.

Dr. ISAAC A. ABT of Chicago said that during the reading of the paper he was reminded of the descriptions given under the title "exudative diathesis," a condition in which there was a predisposing constitutional state associated with certain definite symptoms. Under this term Czerny included exudative inflammatory conditions which might manifest themselves as eczema, scrofula, recurrent bronchitis, asthma, urticaria, etc. The symptoms might be more pronounced after eating eggs or milk, or after mild infection. One must not consider this predisposition a simple anaphylaxis. Many children could tolerate milk and eggs and detoxicated on starches.

Dr. CHARLES GILMORE KERLEY of New York stated that he had read a paper on this subject before the Medical Society of the State of New York, at which time he had presented six cases of children affected with recurrent bronchitis and three in whom asthma was also present. These conditions were different from infectious colds and were nearly always associated with the lithemic, rheumatic, or gouty history. The carbohydrates were at fault, and the children were relieved and gained from three to six pounds in weight by the elimination of carbohydrates from the diet. Starches and vegetables furnished the necessary amount of carbohydrates. Cream was eliminated and only one pint of skimmed milk allowed daily. In addition to the dietetic treatment citrate of soda was given and the bowels were kept open by a suitable laxative. The majority of cases have been benefited by this scheme of treatment.

Dr. SAMUEL S. ADAMS of Washington said that it seemed to him that this was a question of simple idiosyncrasy. Instead of looking for the scientific and the mysterious, we should come back to first principles and take from the diet the article of food which was causing the trouble.

Dr. J. Milton Miller of Atlantic City said that there seemed to be an external factor in some cases that caused irritation. Certain children could not remain at the seashore because of external irritation, but were all right as soon as taken to the mountains.

Dr. John Ruhräh of Baltimore said that it seemed to him that they were confusing two things, acid intoxication and anaphylaxis.

Dr. Percival Eaton of Pittsburgh said that the cases to which he had referred were breast fed and anaphylaxis did not come in. He had seen cases with egg anaphylaxis in which a drop of egg on the hand or face would cause a red spot. Perhaps the cases to which he referred were not the same as those described by Dr. Rachford; it seemed more probable that they were streptococcus or influenza infections.

Dr. B. K. Rachford of Cincinnati, in closing the discussion, said he wished to emphasize the fact that magnesium salts helped to fix the alkali in the tissues. The alkalinity was better kept up when both soda and magnesium were combined. In reference to the criticism that this treatment was palliative it might be observed that one might not always know the cause, but the fact remained that most of these cases responded almost immediately to the alkaine treatment.

Memorial to Dr. Putnam.—Dr. John Lovett Morse and Dr. Charles Hunter Dunn presented this memorial. Dr. Charles Pickering Putnam, for many years a member of this society and its president in 1909, died April 23 last, in his seventieth year. He was one of a family of physicians. He graduated from Harvard College in 1865 and from the Harvard Medical School in 1869. After studying a time in Germany he began to practise his profession in Boston, in 1871. He was a general practitioner, but for many years made a study of pediatrics. He was a lecturer in the Harvard Medical School on diseases of children from 1873 to '75 and a clinical instructor until 1880. At this time he did some excellent pioneer work in orthopedics. He served the Boston Dispensary as district physician from 1871 to 1873 and as orthopedic surgeon from 1873 to 1876. He became physician to the Massachusetts Infant Asylum in 1875, and was also president of its board of trustees from 1898 to 1910. He was chiefly instrumental in the boarding-out system established by this hospital many years ago. Dr. Putnam was from the beginning of his career the leader in Boston in charitable and social work connected with children. He was one of the founders of the Boston Society for the Relief of Destitute Mothers and Infants, which was a pioneer in establishing the policy of keeping mother and child together. He was president of this society from 1904 until his death. He was one of those who, in 1879, took part in the movement for establishing the Associated Charities of Boston, the second charity organization society in this country. He always took a very active part in its work, and was its president since 1907. Dr. Putnam took a leading part for many years in all the movements for the care of the poor and the neglected and delinquent children in Boston. He held many public positions, among the most important of which was that of the chairman of the Board of Children's Institutions, from 1902 to 1911. His work was never properly appreciated and he was frequently misjudged, largely because the public and the politicians were unable to understand the absolute honesty of the man or to realize that he was always working for the good of the community, and not for his own advantage or preferment. He was one of the incorporators of the Boston Medical Library, in 1875, and served upon important committees of this institution until his death. He helped to organize and carry on the Directory for Nurses established by this institution and at the time of his death was in charge of it. This was the first directory established for nurses in Boston. He was a tireless worker and a remarkable organizer. He had the unusual faculty of interesting others and of making them work as hard as he did himself. He was the ideal family physician, beloved of all his patients. One can never quite fill his place for them. No one man can take his place in the community and in public work. It will take many men to do that.

Memorial to Dr. Thomas Morgan Rotch.—Dr. Abraham Jacobi presented this memorial. He said that in 1873 Rotch wrote the "Emigration of the White Corpuscle in Inflammation," an essay to which was awarded the first prize by the Boylston Medical Society for 1873, and in 1878 he wrote "Absence of Resonance in the Fifth Right Intercostal Space, Diagnostic of Pericardial Effusion." The first impressed him as the work of a young man (he was born in 1849) given to study and scientific erudition; the second told of good observation and practical tact. In 1880 at Richmond the Section on Pediatrics of the American Medical Association was formed, of which he was made secretary. The American Pediatric Society was formed in 1888, and he was its second president. One was not unacquainted with the great influence Dr. Thomas M. Rotch has wielded in American medicine, which had to overcome more obstacles than in any country on the face of the globe with the exception of Great Britain. After his return from Europe, in 1876, when he studied in Vienna, Berlin, and Heidelberg, he practised medicine in Boston, always with a view to benefiting the welfare of children and the teaching of their physiology and diseases. The pediatric department of Harvard University owed him everything. This university was the first in America to establish a chair of pediatrics as a proper reward for his incessant labors in that branch of medicine. It happened in connection with that fact, and was characteristic of his modesty, that Rotch asserted that the administration of Harvard was induced to raise that chair to a professorship only by the appreciative mention of pediatric work in the first volume of Keating's Cyclopedia. The list of his medical writings was too voluminous to reiterate. Among the numerous positions that he held were the following: Professor of pediatrics of Harvard University, consulting physician to the Boston City Hospital, visiting physician to the Children's Hospital, medical director of the Infants' Hospital, consulting physician to the Infants' Hospital; he was a member of this and many other medical organizations.

Dr. Rotch was one of those whose greatness was won by hard work in a limited sphere. He appreciated the boundary lines restricting everybody, but felt from the beginning of his career the necessity of constructive work. That was why a large number of his papers were dedicated to the subject of infant feeding. His call to present to the British Medical Association what was considered the American method of infant feeding was the first proof of the impression his personality and teaching had made far and wide, and was followed by the foundation in London of a milk laboratory like that established by Rotch in Boston. It was well known to them all that the first Boston laboratory was not initiated until Rotch had proved to the profession in New York and other cities the desirability of high grade clean milk for infant feeding. That example became the teacher of the profession and the public. For the last twenty years Dr. Rotch was much interested in developing the work of the Infant Hospital, the first in this country to admit patients restricted to the first two years of life. This was only part of the initiative work of Dr. Rotch. It must be left to those who are intimate with his daily life and emotions to record in appropriate terms and with sufficient energy the great merits of Rotch in connection with his teaching and working in the two large hospitals he controlled.

Now the number of constructive clinicians in this country was not large; not one should be buried in silence, least of them a man who had genuine and permanent merit. There were his vast knowledge, enthusiastic industry, clear and logical expression, and other gifts of a great clinical leader. These gifts were increasingly developed with every year of his teaching life. The disproportionate chapters of his great "Pediatrics" were improved from year to year. Gradually it became a book of greater usefulness and proper proportions. With years of learning, guided by his watchful brain, he became more statesmanlike in his views and researches. His big book, the "Living Anatomy and Pathology of Early Life," was pervaded by a humane and humanistic study of the growing child. He gave a distinct discrimination between the actual and chronological ages of the growing child, insisting upon the cautious examination of a child wishing or compelled to do manual labor, according to the anatomical development of his body as exhibited by his osseous growth. It was exactly that class of research and that class of students that would prove the blessing of science and sociology. It was quite possible that Rotch would be remembered by the permanent influence his hospital would exert on the health of thousands of patients and on the ever living stimulation students and doctors would derive from his creations. This influence Dr. Jacobi estimated much higher than the immediate good done to the sick. His value to the profession was greater than that which would come from similar work performed by one equally gifted but more personally

ambitious. Dr. Rotch was a general practitioner, a great teacher, and to his work he added the outflow of his kind and humane heart, and the appreciation of the fact that only good men can be great and good doctors. That is what Hippocrates meant when he said that "where there is love of our calling there is love of mankind," or Nothnagel when he said before nearly closing his eyes: "Only a good man will be a good doctor." That is what Rotch *did*. Though being given to inveterate research he never swerved in pursuing it from the dictates of conscience and humanity. No man who does research work alone or laboratory work on dead tissue alone will ever rival in his results the warm-hearted person who studies the eye of the patient who is under observation, and estimates the innermost folds of a man's heart who clamors for relief. The human suffering body is to men like Rotch much more than a physiological makeup. There was still more to Rotch's credit. There were those who disagreed with him in regard to his theories and teaching on the feeding of babies. Those here and outside who found fault with him should not forget what they inherited from him before he died; our inheritance was the impressive teaching of the necessity of studying the infant and the child. He belonged to the few who taught pediatrics because they could not help it. No disposition of his own made him shoulder the hard work of accomplishing his beneficial ends. Let nobody forget that it was he amongst a few who in America raised pediatrics to the rank of a scientific and humane practice. Dr. Jacobi said he wished his American colleagues would soon appreciate the fact that the young men sent to certain European centers to learn medical science and morals found their goal quite often after their return, when meeting the good and great men sequestered in this and other scientific bodies.

The Clinical Study of Typhoid Fever in Children.—Dr. Henry Dwight Chapin of New York presented this communication, in which he quoted statistics showing that typhoid fever occurred more frequently in children than was formerly supposed. He stated that during the epidemic in the fall of 1913 on the lower East Side of New York City there were 521 cases reported, and of these 221 occurred in children under fourteen years of age; this large proportion of children was probably due to the fact that the milk supply was responsible for the epidemic. The eleven cases which formed the basis of this study were treated in the wards of the Postgraduate Hospital. The duration of the fever was very variable, ranging from seven to forty-two days. In only five cases did the temperature run very high during the active stage of the disease. The diagnosis was confirmed in every case by the Widal test and it is doubtful if without this test and a knowledge of the epidemic most of the cases would have been diagnosed correctly. These cases failed to show the leucopenia that was supposed to accompany typhoid fever. A study of the polymorphonuclears showed what might be considered a polynucleosis when one had in mind the age of the children. The lymphocyte count was more irregular, being normal in only one case. A study of the urine showed that the kidneys were not much affected in this series. The gastrointestinal symptoms were neither marked nor severe. The children seemed to both enjoy and digest the generous diet that was given them. The children were allowed the general ward diet with the exception of meat. This included milk, cocoa, eggs, bread, toast, crackers, cereals, jelly, potatoes, gravy, broths, custard, junket, apple-sauce, orange juice, ice cream, and lady fingers. Nourishment was given every three hours. An effort was made to give them forty calories per kilo body weight, but in not a single instance was it possible to make them take the required number of calories through the febrile stage. In some instances sugar of milk or malt soup was added in order to increase the total number of calories, but this also failed. The most remarkable case occurred in a child of three years who showed a gain of eight pounds after a fever lasting nineteen days. There were no severe complications and no relapses. Of the eleven cases, seven gained in weight during the fever, two showed a very slight loss, and two an appreciable loss. Among the complications were two cases of tonsillitis, two or otitis media, one of hypostatic pneumonia, one pyelitis, and one severe bronchitis. The deduction from this series of cases was in favor of more liberal feeding in typhoid fever.

Dr. L. Emmett Holt of New York asked how long the patients remained in the hospital.

Dr. Henry Dwight Chapin replied that their stay was from three to four weeks.

Dr. Samuel S. Adams of Washington, D. C., said that an analysis of 550 cases in the Children's Hospital under Dr. Acker showed that they were taking about all the foods that Dr. Chapin had mentioned. There was no doubt but that the children did better under modern methods of feeding in typhoid fever and that there were fever intestinal hemorrhages. One point in favor of this method of feeding was the absence of wailing and crying; the children were never hungry. Typhoid fever was never a rare disease and it had long been recognized in children. McPherson recognized it in the seventies, and they had seen typical attacks in infants five and six months old.

Dr. L. E. La Fétra of New York said that, in reference to the difficulty of getting the children to take forty calories per kilo body weight, they had found that after a few days forty or fifty calories were readily taken and sometimes two or three times that amount was taken with benefit.

Dr. Abraham Jacobi of New York spoke of the occurrence of typhoid fever in young babies and said that he recalled a case in an infant fifteen days old in which at autopsy ulcers and Peyer's patches were found. That these were sometimes not apparent was due to the fact that Peyer's patches were not so well developed in young infants. He had heard of several other similar cases.

Circumcision in Masturbation in Female Infants.—Dr. Rowland G. Freeman of New York read this communication. He stated that masturbation occurred with moderate frequency in female infants and was due to adhesions between the clitoris and the surrounding tissues, the clitoris frequently being buried in these adhesions. In a normal robust child they caused little irritation, but in a nervous, sensitive child they might lead to intense irritation. The treatment of this condition was both general and local. The general measures included proper hygiene and the elimination of all sources of irritation, but no cure could be effected by such measures alone. The only satisfactory method of treating this condition was by circumcision, an operation that should be performed by one accustomed to doing it, the foreskin being removed as completely as possible. The result of this operation was most satisfactory. In some instances there was a recurrence of the habit and a reformation of the adhesions necessitating their being broken up a second or third time.

Dr. Abraham Jacobi of New York said that this paper was a revelation to him in that it showed a new cause for masturbation. Irritation leading to this habit might be due to constipation, fissure of the anus, the presence of oxyuris, to vaginal catarrh which was the result of uncleanliness, to irritation resulting from the presence of an oxyuris that had travelled up into the vagina, to cystitis, pyelitis, or stone in the kidney causing peripheral irritation. In his experience masturbation was a disease very frequent before the end of the first year of life.

Wednesday, May 27—Second Day.

Infantile Scorbutus and the Pasteurization of Milk.—Dr. John Lovett Morse of Boston presented this paper, in which he called attention to the rapid increase in the number of cases of scurvy coming to the medical outpatient department of the Children's Hospital during the four years ending in 1913, and to the coincident increase in the amount of pasteurized milk used in Boston during that period. Whereas, in 1904, among 2,579 new cases coming to the hospital, there were three cases of scurvy, in 1913, among 2,416 cases coming to the hospital, there were 21 cases of scurvy. A much smaller proportion of the cases afflicted with scurvy in 1913 were fed on proprietary foods than was the case ten years ago. A study of the diets of the babies developing scurvy in 1914 showed that the milk modifications that were taken were all reasonable ones. While there could be no doubt but that there had been an increase in the number of cases of scurvy in Boston during recent years, it was not proven that this increase had been due to the introduction and the progressive use of commercial pasteurized milk, neither had it been proved that heating the milk, whether to a temperature of pasteurization or of boiling, has anything to do with the etiology of scurvy. They do suggest, however, that there may be some such connection, and that further study along this line seems to be justified.

Dr. Henry John Gerstenberger of Cleveland asked what the results of treatment were in these cases. He had had one case which was cured simply by the addition of orange juice to the diet, without any change in the milk.

Dr. D. J. Milton Miller of Atlantic City said that his experience showed that scurvy was on the increase. He had seen twelve cases in the last two years in private practice. In speaking of this subject a few years ago Dr. Northrup had raised the point that scurvy was frequently not recognized by the average practitioner. In five of his cases there was a history of bipasteurization of the milk. Stapleton, in relating the history of his life in the Arctic region, stated that his men, when the fat supply gave out, developed ravenous appetites that could not be appeased by lean meat, and also scurvy. When a fresh supply of fat was secured their appetites became normal and the scurvy disappeared. This seemed to indicate that a diet not properly balanced might be a factor in the production of scurvy.

Dr. A. D. Blackader of Montreal, Canada, stated that his experience in Montreal coincided with that of Dr. Morse in regard to the increase of scurvy. He had seen an increasing number of cases for the past two years and especially this last winer. He did not alter the food, but simply added orange juice.

Dr. William P. Northrup of New York said that in the paper to which Dr. Morse had referred he had emphasized the fact that after the milk had been pasteurized commercially the lady in the home gave it another boil. The newer practitioners do not know scurvy as the older ones did.

Dr. Isaac A. Abt of Chicago said that some experiments on animals were interesting in this conjunction. Pigeons fed on cereals developed polyneuritis; guinea pigs fed on cereals developed a peculiar susceptibility to scurvy; guinea pigs fed on raw milk had extra brittle bones; some fed on milk heated from 60° to 112° C. got scurvy and those fed on oatmeal and raw milk did not show the disease. Milk heated at 90° F. to which oatmeal was added showed antiscorbutic properties. This brought up the question as to whether cereal could be considered a causative factor in rickets.

Dr. Floyd M. Crandall of New York said that the apparent increase in rickets might be due to the fact that the present generation had not been as alive to this disease as the previous one. This subject was formerly a very popular one for medical literature. He had been surprised that so few papers were written on this subject. This was interesting in connection with the tendency to write along certain lines at certain times; for example, a few years ago there was a flood of literature on the subject of poliomyelitis.

Dr. Thomas S. Southworth of New York said that the practice of feeding infants orange juice had increased just as had the practice of feeding pasteurized milk, and this opened up the question whether there should be a much larger amount of scurvy now than some years ago.

Dr. Rowland G. Freeman of New York said that in New York nearly all the milk sold was pasteurized, and yet he had not seen a case of scurvy all winter.

Dr. Godfrey R. Pisek of New York said he wished to confirm what Dr. Freeman had said in regard to the absence of scurvy in New York. He had not seen a case the past year.

Dr. Henry Heiman of New York said he also could confirm what had just been said. He had not seen a case of scurvy in New York recently. Scurvy was due not so much to pasteurized milk as to artificial foods. Scurvy was a form of food poisoning. Rickets in his experience had occurred after the use of pasteurized milk, but equally as often with other forms of feeding.

Dr. J. P. Crozer Griffith of Philadelphia called attention to an investigation of this subject by a special committee. This committee found that there was nothing wrong with the food, but it did not get much further. A change of food was what was needed, but as to what that change should be could not be predicated. Ten cases occurred in infants that had been breast fed and no one could tell what was wrong. There must be a scientific basis to account for this condition, but as yet we could not blame pasteurized milk, sterilized milk, or any other single food.

Dr. Samuel McC. Hamill of Philadelphia said he would like to know at what temperature the milk was pasteurized in these cases. One should be careful in making statements about pasteurized milk when it was so necessary to pasteurize it in order to protect children.

Dr. John Lovett Morse of Boston, in closing the discussion, stated that the milk in his cases had been pasteurized in different ways, and possibly some of it was not pasteurized. All the children were given orange juice. Sometimes they did not change the food, but allowed the baby to have the same formula, but did not heat the milk. With regard to the failure to recognize the disease, physicians ought to know more about it than formerly; much attention was paid to this subject at Harvard. After reviewing the literature it must be confessed that there was nothing in the evidence that pasteurization had any effect on the nutrition, yet here were these figures, and there was something in this increase in this disease which they had not explained.

Experiences with the High Caloric Diet in Typhoid Fever in Infants and Young Children.—Dr. L. E. La Fétra and Dr. Louis C. Schroeder of New York presented this communication, which was based on the observation of forty-eight cases. The children were fed at three hour intervals, beginning at 6 A. M. and continuing until 9 P. M. The articles given were very much those prescribed for a child in health, with the exception that the only meat used was creamed chicken. To increase the caloric value of the liquid food, lactose, cocoa, and cream were added. In no case was an exclusive milk diet given. Eggs and toast were offered from the beginning. The amount of food taken depended to a great extent on the nurse's tact and encouragement. The number of calories that were actually taken after the first few days and that seemed from a clinical point of view to have been actually utilized was from 100 to 300 calories per kilo body weight. Unless toxic nervous symptoms were present the fever did not prevent the taking of a generous diet; as the temperature fell the amount of food taken was greater. The diagnosis was established by positive Widal reaction in 44 of the 48 cases and by positive blood cultures in 36 cases. The length of time in the hospital averaged 28 days, the extremes being 13 and 79 days. The general condition of the patients was remarkably good. The so-called typhoid state occurred in a much smaller percentage of cases than with the older methods of treatment. Abdominal distention was present in only six cases and in but one of these was it severe or troublesome. Five of the patients had blood in the stools at some time in the course of the disease, but in only two cases were the hemorrhages severe. One patient was transfused three times, lost more weight than any other case, and during his convalescence took the largest number of calories that they had ever seen recorded, viz. 8,000 in twenty-four hours. There was not the slightest doubt but that the severe nervous symptoms seen in the late stages of the disease heretofore were due to starvation and the consequent increased toxemia. Pneumonia and bronchopneumonia complicated three cases, and in the only death that occurred it was found at autopsy that the fatal issue was due to the pneumonia. There were but three relapses and one recrudescence. During the course of the fever 60 per cent. of the patients gained in weight. This was the most remarkable fact in this series. If one considered the weights of the patients at the time of leaving the hospital it was found that 92 per cent. had gained in weight.

Dr. Frank S. Churchill of Chicago asked Dr. La Fetra whether he had noticed any connection between the intestinal hemorrhages and the high caloric diet.

Dr. Charles Gilmore Kerley said he had been using a diet similar to the one described but did not allow meat until the third week. He had long been advocating a more generous diet in typhoid fever. One found much less tympanitis since abandoning the milk diet. An exclusive milk diet was the chief means of producing tympanites.

Dr. John Lovett Morse of Boston said he had learned his lesson as to the need of a more generous diet twelve years ago during an attack of the typhoid fever and had been giving a more generous diet ever since. With the high caloric diet one would not have the constipated stools that one got with the exclusive milk diet. They were feeding typhoid fever patients a varied diet and trying to keep the calories as high as Dr. La Fetra did. It was difficult to give the high caloric diet during the febrile period and the dietetic treatment of the disease should be divided into two periods, the febrile and the postfebrile.

Dr. L. E. La Fétra of New York said that in reference to the diet during hemorrhage, it was not very high at that time. In the boy with hemorrhage as much food was given as he would take when his temperature was 103° F. Dr. Morse was right in making the distinction between the two periods in feeding.

The Gaseous Metabolism of Infants.—Dr. Francis G. Benedict and Fritz B. Talbot of Boston presented this

communication, which was read by Dr. Talbot. He gave a complete historical review of all the history on gaseous exchange and the calorimetry of infants and presented several of the important problems in this field. A respiration apparatus, measuring simultaneously carbon dioxide production and oxygen consumption and provided with a sensitive arrangement for registering automatically and graphically the slightest body movement, was used to study fifty-eight infants during approximately 1,000 periods of observation. Continuous records of the pulse rate and a graphic registration of the degree of muscular repose enabled many important correlations with the respiratory studies. A series of twelve hour continuous pulse records, accompanied by ocular observations of the degree of repose, showed a sudden and considerable increase of the pulse rate with crying or nursing and a rapid return to the low level with cessation of crying and feeding. A comparison of the pulse rate with muscular activity as determined by the kymograph records of a swinging crib showed invariably a close agreement. The metabolism also increased or decreased as the pulse rate and activity increased or decreased. Distinct evidence of an increased pulse rate and metabolism independent of external activity was interpreted as being an indication of internal work and suggested the pulse rate as an indication of internal work. Particular stress was laid on a comparative study of the basal metabolism of the infants, *i.e.* the metabolism during complete repose as shown by the kymographic records. Under these conditions it was found that while in general the smaller the infants had the smaller total metabolism, there were a sufficient number of striking exceptions to prevent the formulation of a definite law. Similarly there was no striking uniformity in the metabolism per kilogram of body weight, although with normal children the plotted chart gave indications of an approximately regular line. As many of the infants were under weight, the total metabolism was compared with the normal weight for the age, but no approach to uniformity or regularity was apparent. A discussion of the supposed relationship between body surface and metabolism and a critique of the methods used for measuring body surface introduced the discussion of the values found in these infants. No relationship was found between the age of the infants and the heat produced per square meter of body surface, nor could any relationship be noted between the heat production per square meter of body surface and the actual body weight, the normal weight for the age, or the expected body weight. Evidence secured with normal and atrophic infants of different ages and weights was presented to show that the active mass of protoplasmic tissue determined the heat production. This active mass of protoplasmic tissue might be stimulated to a greater or less cellular activity, the intensity of the stimulus being indicated by the pulse rate.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

SOUTH DAKOTA STATE BOARD OF MEDICAL EXAMINERS.

January 13 *and* 14, 1914.

(*Concluded from page* 404.)

EYE, EAR, NOSE, AND THROAT.

1. Treat a case of severe corneal ulcer. 2. Describe and give treatment for dacryocystitis. 3. What do you understand by the following: hypopyon, Argyll-Robertson pupil, mydriasis, presbyopia, ptosis? 4. What would be your treatment for penetrating wound of the cornea? 5. Give four common symptoms caused by nasal obstruction. 6. Give symptoms and treatment for hypertrophied turbinate. 7. Treat a case of chronic otitis media. 8. Describe the Eustachian tube, giving anatomy and function. 9. Give your method of differentiation between middle and internal ear disease. 10. Give three common causes for deafness and treat a given case.

SKIN AND GENITOURINARY.

1. Diagnose secondary syphilis and outline treatment. 2. Give causes and treatment of orchitis. 3. Give etiology, diagnosis, and treatment for urticaria. 4. Give symptoms, diagnosis, and treatment of urethral stricture. 5. Give etiology, diagnosis, and treatment of erysipelas.

HYGIENE AND SANITARY SCIENCE.

1. How would you fumigate a residence containing approximately 10,000 cubic feet of space? Name materials employed and amount of each. 2. Describe how sewage is purified in sedimentation tanks. 3. Describe the life-cycle of the common house-fly. 4. Instruct briefly a patient suffering from pulmonary tuberculosis as to the precautions he should adopt to avoid the spread of the disease. 5. Instruct briefly your nurse attending a case of diphtheria.

MEDICAL JURISPRUDENCE.

1. A, attending a confinement case, finds it necessary to use instruments and calls B to administer the anesthetic. A does not sterilize the instruments and the patient becomes infected and brings suit to recover damages. Does B share the responsibility with A? 2. A, in performing a laparotomy relies on B, a trained nurse, to pack the abdominal cavity with sponges. B also removes the sponges, but in so doing, one is overlooked. Who is liable: A, the surgeon, or B, the nurse? 3. If in your practice you are called to treat an injured wrist, said injury, according to your judgment is a severe sprain and you treat it accordingly, using reasonable care and skill. Later the patient calls another surgeon who discovers the injury to be a fracture. Would you be guilty of malpractice? 4. Can an unauthorized or unlicensed physician maintain an action for libel or slander against one who charges him with misconduct or incapacity in the discharge of his professional duties? 5 Would a physician be liable who takes an unprofessional, unmarried man with him to attend a case of confinement when there is no emergency requiring his presence?

ANSWERS.

EYE, EAR, NOSE, AND THROAT.

1. *Management of corneal ulcer:* The treatment consists in putting the eye at rest, instilling atropine, and the application of a bandage. Leeches to the temple will relieve the pain. Hot compresses have the same effect. The eye should be douched with sublimate solution, 1:5000, and iodoform dusted upon the cornea. Stronger sublimate solution, boroglycerid 50 per cent., and formalin 10 per cent. are sometimes necessary. Cauterization is occasionally indicated. If perforation seems probable, it should be hastened by a puncture.—(*Cyclopedia of Medicine and Surgery.*)

2. *Dacryocystitis.* "The initial symptoms are conjunctivitis, local pain, and redness of the skin. The distended sac soon appears as a tumor involving the tissues near the inner canthus of the eye. If left to itself, this tumor may ulcerate and the pus burrow through the skin, establishing what is known as a lacrimal fistula, which may remain a lifetime and become in itself a safeguard against a new attack. Often the distended sac loses its elasticity and becomes a permanent tumor. *Treatment*—Any nasal affection should be corrected, and a free passage for tears into the nose established. The latter is generally effected by the passage of sounds. Bowman's sounds or probes are usually employed. The canaliculus should be slit, and the following day the passage of probes commenced."—(*Cyclopedia of Medicine and Surgery.*)

3. *Hypopyon* is a collection of pus in the bottom of the anterior chamber of the eye. *Argyll-Robertson pupil* is a condition in which the pupil accommodates for distance but not for light. *Mydriasis* is dilatation of the pupil. *Presbyopia* is loss of accommodative power of the eye, occurring normally in advanced life. *Ptosis* is drooping of the upper eyelid.

4. *Penetrating wounds of the cornea* are serious owing to the danger of prolapse of the iris and injury to the deeper parts. They should be treated by thorough cleansing, atropine or eserine, according as they are central or peripheral, and a pressure bandage. If extensive, the edges may be stitched together.—(*From* May's *Diseases of the Eye.*)

5. (1) A feeling of fulness across the bridge of the nose; (2) mouth-breathing; (3) loss or diminution of the sense of smell; (4) aprosexia.

6. HYPERTROPHIED TURBINATE. *Symptoms:* Nasal obstruction, odor on the breath, increased secretion, mouth breathing, nasal twang to the voice, congestion of nasopharynx. *Treatment:* Cleansing the nose with a spray, cauterization of the turbinate, or removal of a portion of the hypertrophied turbinate.

7. *Treatment of chronic purulent otitis media:* "Cotton must never be worn in the discharging ear. The discharge must be mopped out, but if very thick and copious, syringing by means of sterile water or sterile water containing salt (gr. 5-5 1) or carbolic acid (1 : 40), once or twice in 24 hours in bad cases is permissible. After mopping the ear, 10 drops of an antiseptic solution may be instilled. Formalin solution (1 : 1000-1 : 2000), carbolic acid solution (1 : 40), or, if granulations are present, absolute alcohol, may be dropped in and allowed to remain for a few minutes, and then turned out into a towel. This treatment should be continued once or twice a day in very bad cases, and less often when the discharge decreases. If, after several months, improvement does not take place removal of the ossicles under general anesthesia may be necessary."

Treatment of chronic catarrhal otitis media should be directed to the nasopharynx, and should be unirritating in character. The condition of the general health should be improved. Oleaginous should be preferred to watery sprays. Inflations of the tympanum should be avoided. When the nasopharyngeal condition has improved, gentle pneumomassage of the membrana tympani by means of the Siegle pneumatic speculum may be performed. If, in spite of this conservative treatment, the condition becomes worse, resort may be had to the removal of the incus."—(*Pocket Cyclopedia.*)

8. The *Eustachian tube* is a canal which connects the tympanic cavity with the nasopharynx. It is an inch and a half in length. The tympanic end is osseous; the pharyngeal end is cartilaginous. The diameter of the tube is not uniform, being largest at the pharyngeal end, and smallest at the junction of the bony and cartilaginous portions. Its function is to afford equalization of air pressure on each side of the membrana tympani, and to afford drainage for the middle ear.

9. "In order to make a differential diagnosis between middle-ear and internal-ear affections, it may be stated, as a general rule, that (1) in diseases of the inner ear, low-toned tuning-forks are heard better than the higher ones by aerial conduction, if any fork is heard at all; while in diseases of the middle ear, if the nerve be not affected, the reverse is true—*i. e.*, the higher forks are heard better. (2) In disease affecting the labyrinth or internal auditory nerve, the bone conduction becomes very much impaired or lost, as shown by Rinné's or Weber's tests. In the case of a person with normal hearing, a vibrating tuning-fork should be placed on the mastoid process, and the surgeon should be notified by a signal from the patient when he ceases to hear the sound. If the fork is then held close to the meatus, it will still be heard several seconds longer. In middle-ear or external-ear diseases the tuning-fork will be heard much longer when placed on the mastoid than when held close to the meatus. In a case of deafness in which the labyrinth is involved, the bone conduction becomes much impaired or lost altogether. Notes of a low pitch are, as a general rule, heard better than high ones. In consequence, the watch is not heard as well as the voice. . . . When the acoumeter is not heard by bone-conduction there is a reasonable certainty that the internal ear is affected. It must not be forgotten, however, that diminished bone-conduction is frequently observed in cases of adhesive catarrh of the middle ear as a result of secondary implication of the internal ear, or of intralabyrinthine pressure."—Bacon's *Manual of Otology.*)

10. *Three common causes of deafness:* Impacted cerumen, inflammation of the middle ear, and perforation of the membrana tympani.

Treatment consists in removing the cause, if possible. *Impacted cerumen.* Disintegrate it with hydrogen peroxide, which is left in the ear a few minutes, and followed by an irrigation of warm water.

SKIN AND GENITOURINARY.

The second stage of syphilis is characterized by: Sore throat, mucous patches; the skin lesions or syphilides, which are characterized: By not itching; by being of a coppery or raw ham color; by being painless; by polymorphism, macules, papules, pustules, etc., being present at the same time; by being generally symmetrical. In this stage may also appear: Iritis, periostitis, alopecia, fever, and insomnia.

Treatment consists of mercury during the early part of this stage, and iodide of potassium (either with or without mercury) during the latter part of the stage; salvarsan (either intramuscularly or intravenously) may be used in this stage. The general health must be maintained.

2. ORCHITIS. *Causes:* Injury, rheumatism, gout, mumps, epididymitis, syphilis, tuberculosis, and other infections. *Treatment:* Rest in bed, elevation of the scrotum, application of fomentations or of lead water and laudanum.

3. URTICARIA. An inflammatory affection of the skin, characterized by the formation of evanescent whitish and pinkish elevations, attended by intense itching. It usually arises from some disturbance of the alimentary canal. Certain articles of food, such as lobsters, crabs, sausage, strawberries, etc., and certain drugs, as quinine, copaiba, cubebs, salicylic acid, etc., are prone to produce the affection.

The treatment consists in the use of emetics, laxatives, and enemas to expel the offending substances. Intestinal antiseptics should then be administered. Salol or phenacetin may be given in subacute cases. Lotions containing carbolic acid, menthol, liquor carbonis detergens, benzoic acid, sodium carbonate, etc., may be used to relieve the itching.—(*Pocket Cyclopedia.*)

4. *Urethral stricture* is characterized by difficult and slow micturition, dribbling after micturition, retention of urine, irritability of bladder, and urethral discharge. There is obstruction to the passage of a catheter or sound. *Treatment:* Gradual dilatation, continuous dilatation, excision of the stricture, or urethrotomy.

5. ERYSIPELAS. *Etiology:* The *streptococcus erysipelatis,* which gains admission through a wound or abrasion. *Diagnosis* is made by the very high fever, crimson flush around the wound, the red area is swollen and has a raised edge, great swelling and enlarged glands are observed. *Treatment: Prophylaxis.*—Secure the asepsis of all wounds. All cases should be isolated to prevent the infection of others. *Local.*—In most cases all that is necessary is to apply lead, or lead and opium lotion. This has no curative action, but it relieves the stiffness and burning. Other applications, such as ichthyol, are used, but do not hasten the termination of the process. A form of treatment which aims at getting ready a supply of phagocytes at a distance of 2 inches from the spreading margin is the most promising. The skin is irritated by free scarification, and the tissues then become infiltrated with leucocytes, which are ready to attack the cocci when they spread in this region. The part is kept covered with carbolic fomentations (1 in 40). *General.*—Good food and stimulants. The bowels should be kept acting by magnesium sulphate, and 2 to 4 grains of quinine with 15 minims of the tincture of perchloride of iron are generally given every four hours. Antistreptococcic serum sometimes is very useful, either injected or given by the rectum. The treatment of cellulo-cutaneous erysipelas is that of cellulitis."—(*Aids to Surgery.*)

HYGIENE AND SANITARY SCIENCE.

1. "The clothing and bedding which are to be disinfected by means of steam should be carefully wrapped in cloths saturated with 1 per cent. carbolic acid solution, placed in a wagon, and taken to the disinfecting station. After the bed has been stripped, all refuse matter, paper, and articles of little value are wrapped in cloths saturated with carbolic acid and burned in a stove or furnace. The floor, doors, windows, furniture, and the walls for a distance of 1½ meters from the floor should be washed with 5 per cent. carbolic acid solution. The walls and ceiling of the room should subsequently be sprayed with 1:1000 bichloride of mercury solution. If the walls are papered, it is advisable to remove carefully the paper before beginning the disinfection. The room is then closed as tightly as possible and disinfected by means of formaldehyde."—(Bergey's *Hygiene.*)

2. "The solid parts of the sewage may be partly removed or separated from the liquid mass by mechanical precipitation or sedimentation, and the liquid part may then be drained off into rivers, etc., while the solid part is utilized in one way or another. The precipitation of the solid particles of sewage is accomplished either by gravity in large tanks, at the mouths of sewers, or by means of screens, revolving blades, and other devices. Chemical means may be employed to assist or to cause precipitation; and the iron salts, copper sulphate, lime, alum, etc., have been used for the purpose of forming flocculent precipitates, which, on settling, are supposed to clarify the sewage from most of its solid and harmful parts."—(Price's *Hygiene and Public Health.*)

3. LIFE-CYCLE OF THE COMMON HOUSE-FLY. *Egg:* Dull chalky white; elongate cylindrical oval, rather more

pointed at front end; about 1/25 to 1/20 inch in length; laid in small masses, usually in crevices, in large accumulation of horse manure and house-refuse. Hatches in from eight to twenty-four hours.

Larva: A white footless maggot, of the type known as a "gentle"; when full grown, from 1/4 to 2/5 inch in length; can be distinguished from similar larvæ by examining under a microscope or powerful lens the posterior (broader) end of the body, when the openings there situated, through which the larva breathes, will be seen to be in the form of two pairs of very sinuous clefts, each pair of clefts being surrounded by a thickened plate, with a straight inner and semi-circular outer edge. Under favorable conditions (food-supply, temperature, moisture), duration of larval stage may be as short as four to five days.

Pupa: Dark red; barrel-shaped, regularly cylindrical, but tapering somewhat in front; 1/5 to rather more than 1/4 inch in length. Duration of pupal stage, under favorable conditions, from three to five days.

Perfect insect: Normal length about ¼ inch; mouse gray; thorax marked with four narrow, black, longitudinal stripes, sharply defined—at least, in front; sides of basal half of abdomen in male, and frequently in female, ochraceous buff; end of abdomen with a yellowish shimmer; space between eyes in male scarcely one-fifth, in female nearly one-third, of total width of head; proboscis not visible from above; end of fourth longitudinal vein in wing bent sharply upwards, so as to nearly meet the vein above it. Most numerous in houses from July to September, but still common in October. May live from six weeks to four months. The winter is passed in this stage.—(*Aids to Tropical Hygiene.*)

4. *Hygienic precautions to be taken in case of tuberculosis:* "The patient's quarters should be free from dust, and admit of spending many hours daily in the open air in all weathers, properly sheltered, and, if very ill, lying wrapped in a hammock or reclining chair. His bedroom should be well aired at night, draughts being avoided. The room should be uncarpeted and free from hangings. It should be often cleaned and periodically disinfected. All sputum should be collected in paper spit-cups, which should be burned daily. Smoking should be forbidden. Harm is done by any exercise which results in fatigue, and while fever exists it should not be attempted at all. Patients should be taught the necessity of practising lung gymnastics and breathing only through the nose, which should be kept clear and free from occlusion by secretions, or an hypertrophied catarrhal mucosa. . . . The clothing should be woolen, but not too heavy, or sweating is increased; and a flannel nightgown and loosely knit leggings should be worn at night in cool weather. The skin should be cleansed by daily sponge-baths of lukewarm alcohol and water."—(Thompson's *Practical Medicine.*)

5. The patient is to be kept isolated, and in bed; the room to have as few hangings, etc., as possible; the nurse, physician, and any other in contact with the patient to disinfect their hands, and avoid the spray from the patient's expectoration; the sputum, nasal discharge, linen, utensils, etc., to be disinfected. The nurse should also bathe and use a disinfectant, and change her clothes before going out.

MEDICAL JURISPRUDENCE.

1. B. does not share the responsibility with A.
2. A., the surgeon, is liable.
3. No; you are only expected to use "reasonable care and skill."
4. No.
5. Yes; the physician is liable.

Empyema of the Antrum with Infection of the Nose and Cheeks.—H. J. Davis reports the case of a woman, aged 30, who had redness, infiltration, and edema of the nose and both cheeks of six months' duration. The author mistook the case for one of lupus erythematosis. There were shadows on transillumination, but this might have been accounted for by the extreme thickness of the infiltrated integuments. Pernet who saw the case, disagreed with the author's diagnosis, and suggested an empyema of the antrum and a septic infection of the integuments therefrom. This on intranasal puncture proved to be the case. The condition is one of chronic symmetrical lymphangitis with blocking of the lymphatics from a septic focus in the antrum. —*Proceedings of the Royal Society of Medicine.*

Therapeutic Hints.

Solutions Containing Glucose.—J. Baumel and M. Cathola cite the following formulæ of hypertonic solutions containing glucose, as recommended by Fleig:

℞ Pure crystallized glucose, 300 grams.
Distilled water, ad 1,000 c.c.

℞ Pure crystallized glucose, 150 to 200 grams.
Anhydrous sodium chloride, 3 to 5 grams.
Sodium glycerophosphate, 5 to 7 grams.
Distilled water, ad 1,000 c.c.

℞ Pure crystallized glucose, 100 grams.
Sodium bicarbonate, 30 grams.
Distilled water, ad 1,000 c.c.

℞ Theobromine, 1 gram.
Trisodium phosphate, 4 grams.
Pure crystallized glucose, 120 grams.
Distilled water, ad 500 c.c.

℞ Diuretin, 2 grams.
Pure crystallized glucose, 120 grams.
Distilled water, ad 500 c.c.

℞ Caffeine, 0.50 grams.
Pure crystallized glucose, 120 grams.
Distilled water, ad 500 c.c.

The dose of any of the above is 250 c.c. injected hypodermically or intravenously twice a day, every other day.—*Progrès Médical.*

Calcium Salts in the Treatment of Progressive Deafness.—Gradenigo states that the observation has frequently been made that deafness occurs in some women during or following pregnancy or lactation, apparently the result of lesions of the osseous capsule of the labyrinth similar to those of osteomalacia. Some observers attribute this deafness to functional changes in the glands of internal secretion, especially of the thyroid and parathyroid. Other observers believe that the deafness is the result of an otosclerosis of degenerative origin, and is allied to certain forms of congenital deaf-mutism. Gradenigo inclines to the view that the deafness of pregnancy and lactation is the result of changes in the thyroid and parathyroid and for this reason finds a rational basis for the administration of calcium salts as a therapeutic measure. In a number of cases this method of treatment produced excellent results. He employed daily doses of about 3 grams of the chloride or lactate of calcium. The hypodermic administration is dangerous, frequently leading to abscess formation.—*Presse Otolaryngologique.*

Ultraviolet Rays in the Sterilization of Organic Extracts.—M. J. Lematte calls attention to the difficulty of preparing organic extracts for hypodermic administration in such manner as not to destroy their specific properties. There are valid objections to the use of heat, the addition of chemical antiseptics, etc. The author employs a quartz mercury-vapor lamp of the Cooper-Hewitt type by means of which he is able to sterilize solutions of pepsin, pancreatin, etc., without altering their activity.—*Bulletin Général de Thérapeutique.*

The X-Ray Treatment of Hypertrophy of the Thymus.—A. Weil reports that he obtained a diminution in the size of the thymus in eight infants in whom this method of treatment was employed. The doses of the radiations were relatively quite large. Filters of a thickness of 4 millimeters were used and doses of *x*-rays of 6 or 7 H were given.—*Gazette des Hôpitaux.*

THYROID DEFICIENCY.*

BY E. HERTOGHE, M.D.,

ANTWERP, BELGIUM.

CORRESPONDING MEMBER OF ROYAL ACADEMY OF MEDICINE OF BELGIUM.

MYXEDEMA in the severe form was discovered and first studied in England. It is now a well-known pathological entity all over the world and of it I could say nothing but what you know perfectly well. But I will insist upon the mild forms because they are not so well outlined and very often escape the attention of the medical man. I called it when I described it for the first time 1899[1] mild myxedema, myxedema frustum, or benignant chronic hypothyroidism. The conception of mild myxedema was at first strongly opposed because the symptoms were so numerous, that is to say, because the symptomatological range was so great and extended to every organ of the body. Just lately Dr. Leonard Williams of London has said: "The idea of benignant chronic hypothyroidism is simple enough, but the symptomatology is a perfect maze." This is not the fact, provided we begin with a clear understanding of the lesion caused by thyroid want.

If we knew exactly the function of the thyroid gland we would no doubt be able to deduct immediately the symptom of a diminished or impoverished secretion; but we do not. However, we know something. We know that without the thyroid stimulus no cell, whatever it may be, can attain its morphological perfection—the perfection needed for good work, muscular, nervous, connective, glandular, or bone. The proof thereof is that a child born with congenital want or a child deprived completely by an operation of its thyroid gland does not grow, or grows very little. Give it a few doses of thyroid extract and it will begin to develop; stop the supply and immediately progress is stopped.

We know something more: When a cell has done its duty for some time it decays, it is no longer desirable. It must be taken to pieces and eliminated through various channels—bowels, kidneys, lungs—especially under the form of urea. When thyroid supply is scarce the carrying away of the cellular waste matter is slow and incomplete—mucin, fat, and other principles accumulate on the spot, and there form an infiltration and edema of a special kind—hard, non-depressible—and therefrom comes the name of myxedema.

Infiltration Is the Constant Lesion of Thyroid Deficiency.—It may be obvious or it may be slight, but it is always there. If a patient, swollen with this special edema, takes thyroid extract he immediately eliminates a great quantity of urine and urea. He loses in weight, the cellular waste matter is carried away, and when he has got rid of the whole residual stock you may give him doses ten times stronger and he will lose no more. We may sum up and say, thyroid secretion is necessary to the building up and to the dismantling of our tissues—of all our tissues; and, therefore, the want of it finds an echo in all our organs without any exception.

All the infectious diseases of early age and of later on fall heavily on the vitality of the thyroid gland. Acute rheumatism of the joints has a most nefarious influence and causes even after years the outbreak of severe forms of myxedema. And, what is more, all the great causes of pathological disturbance, tuberculosis, syphilis, paludism, alcoholism, chronic starvation, and consanguinity hit their first blow on the thyroid system, and the theyroid deficiency thus brought on comes down fatally on the offspring.

The child shown in Fig. 1 is a remarkable instance of hereditary syphilis and thyroid weakness. The father married shortly after having contracted syphilis. The result you see here—growth stopped, cretinous appearance; observe also the result of medication.

If we had seen such a patient some ten or fifteen years ago we would have no doubt diagnosed hereditary syphilis, but there would have ended our healing power—neither iodine nor mercury would have restored the child to normal growth and health. But now that we know that the growth has been stopped on account of the syphilitic toxin having dried up the thyroid well, we act in consequence and have a successful medication, that shows the usefulness of the hypothyroid notion.

The litle girl shown in Fig. 2 is a case of thyroid weakness caused by hereditary paludism. The mother while pregnant underwent several attacks of intermittent fever. She herself had a weak thyroid. The paludic poison added to her natural disposition had the result of impairing the thyroid powers of the child, and it was born a cretin. This case looked at as merely paludic was hopeless. Seen in the light of thyroid weakness we get a good result.

The boy shown in Fig. 3 was twenty-one years old. He was a perfect dwarf, absolutely childish, and without any intellectual development. Mother healthy. Father died from pulmonary consumption a few days before the child was born. This may be considered as a case of hypothyroidism and tuberculous heredity.

Let us bear in mind that we are inheritors of a great number of generations. Our blood is a mixture of good and bad qualities that our forefathers have left us while struggling with innumerable causes of diseases of all sorts. From

*A lecture delivered at the New York Polyclinic Medical School and Hospital, April 14, 1914.

all this we may conclude that thyroid weakness is very frequent, at least in a mild form.

Now I must say that thyroid weakness is not synonymous with cretinism. Incomplete forms will go very well with a fairly active and busy life;

a *b* *c*

FIG. 1.—Hereditary syphilis. *a*, Arrest of growth, age 10½, height 3 ft. 2½ in.; *b* and *c*, influence of thyroid feeding after 1 and after 2 years.

some of these patients are indeed very intelligent. I wish to draw your attention to these social forms because they are very common, and because the exact knowledge of them enables us to grasp the cause and decide the successful treatment of a large number of pathological conditions for the occurrence and treatment of which we are otherwise unprepared.

We will now follow up the idea of infiltration which is brought on by thyroid insufficiency, and consider the consequences in various tissues of the body.

Muscles.—The cell loaded with fat and mucin is increased in size so that its contraction is delayed in onset and slow in execution. Muscular action then becomes painful, accompanied by stiffness and dread of movement. The connective tissue sheath which supports the contractile elements and connects the muscles with the tendons, aponeuroses, and articular ligaments is equally infiltrated, and this adds to the difficulty of movement. This applies alike to non-striped and voluntary muscle.

This muscular infiltration shows itself subjectively by rheumatoid pains, which must not be confused with rheumatism, due to causes with which we are not here to be concerned. The statement made by some writers that thyroid extract cures nodular rheumatism, chronic or otherwise, should, therefore, be accepted with reserve. Thyroid extract relieves pain in the muscles, joints, and ligaments only in so far as this depends on thyroid deficiency; that is, it is due to the specific myxedematous infiltration, and it acts only by causing absorption of that infiltration. We must remember that thyroid extract is essentially a specific and can act favorably only where there exists an inactivity or weakness of the thyroid.

Let us take another example. The nerve cell, whatever may be the degree of myxedematous cachexia, is never destroyed as in a hemorrhagic focus or embolic necrosis. Its nutrition and excretion are simply hindered. It is infiltrated and at the same time compressed by the infiltration of its supporting connecting tissues. The transmission of motor, sensory, and voluntary impulses is thereby delayed but not abolished, and the reflexes are sluggish but present.

The discomfort of the nerves shows itself by neuralgias and even by shooting pains of a neuritic character; the distinction between these two kinds of pain being well known to the patient. Cardiac pain is also present with radiations into the brachial plexus simulating attacks of angina.

The central nervous system exhibits early evidence of infiltration, however slight it may be. In well-marked myxedema, vertigo, dizziness, noises in the ears, headache, migraine, loss of memory, mental confusion, depression, melancholia, loss of consciousness, loss of balancing power, sudden falls, somnolence, attacks of coma, which may be confused with the serous apoplexy of Bright, with all the more probability that there is usually some albuminuria.

In mild myxedema the list is not so formidable. One should remember the morning headaches and tendency to migraine, vertigo, and noises in the ears.

Even the bone does not escape the consequences of thyroid defect. Every surgeon knows that in certain persons fractures unite imperfectly or not at all, and thyroid extract is given to avoid complication. If one carefully examines such patients, those at least who benefit by it, there will always be found some more symptoms of thyroid deficiency.

Cartilaginous tissue also gives clear evidence of this specific cellular infiltration. On moving the joints which are stiff and painful the application of the hand detects a peculiar sensation resembling the crackling of crushed snow which is almost pathognomonic. This is well felt in the knee joint. Sometimes the patient himself feels and hears a crepitation in the joints of his cervical vertebræ. These joints symptoms were described first by Professor Verriest in connection with a case of myxedema shown to the Royal Academy of Medicine of Belgium in 1886.[2]

These painful affections of the joints improve very slowly and are the last symptoms to disappear. An ecclesiastic, after several months' treatment for very pronounced myxedema, still complained of the stiffness of his knees which rendered ritual genuflection very difficult, but which ultimately completely disappeared. This delay in functional restor-

FIG. 2.—Hereditary paludism. *a*, Arrest of growth, age 8 years, height 2 ft. 10 in. instead of 3 ft. 10 in.; *b*, *c*, *d*, influence of thyroid feeding, after 1, 2, 5 years.

ation may perhaps be explained by the slowness of the nutritive exchanges in cartilage.

The glandular tissues which play so important a part in the organism also present infiltration both of their secreting elements and the supporting con-

nective tissue. The secretion of sweat is completely abolished.

There is considerable congestion of the liver, the hepatic cells secrete badly, while the canaliculi are compressed. Bile passes into the circulation,

Fig. 3.—Hereditary tuberculosis, thyroid weakness. Arrest of growth; influence of thyroid feeding, after ½, 1, and 2 years.

causing the characteristic amber color of the skin. Biliary calculi are also common.

The scanty intestinal secretion along with the muscular weakness of the visceral walls causes obstinate constipation, which in turn leads to fermentation with the formation of an abnormal quantity of gas, thus producing meteorism and abdominal distention with noisy eructations from the stomach.

The alterations of epidermic and epithelial coverings deserve special notice. The insufficiently nourished epidermis undergoes early desquamation; the hair falls prematurely. In milder cases the hair is poor, brittle, and becomes early grey, while the beard is thin and straggling. The nails are striated and brittle, and in severe cases split and destroyed. The teeth are almost always in a deplorable condition, exposed, decayed, and covered with a greenish tartar. The gums are red and irritated, forming polypoid projections between the teeth. The eyebrows are thinned, especially in their outer thirds, giving the face a somewhat silly expression. The eyelashes are also shed, leaving the eyelids unprotected against the erosive action of the tears. This blepharitis of thyroid origin is sometimes seen in old persons. In a case which had resisted all other means of treatment, a radical cure was obtained in a few days by the local application of adrenalin and the administration of thyroid extract. The whole skin is thickened, infiltrated, cold, and easily attacked by such affections as eczema, psoriasis, and alopecia. The eczematous condition of the scalp in young infants, known as the "milk crust," which is alike the despair of mothers and doctors, yields rapidly to a few doses of thyroidin combined with arsenic, when this affection is associated with thyroid defect, and the same can be said of psoriasis and of certain forms of alopecia.

The little boy pictured in Fig. 4 had lost all his hair. I should never have suspected thyroid deficiency in this case if the mother had not evidently been under thyroid distress. The result of thyroid treatment on growth and alopecia is well shown.

The mucous membrane of the mouth, lips, tongue, nose, pharynx, larynx, ear and esophagus are also infiltrated.

The vaginal mucous membrane is softened and infiltrated, giving on digital examination a sensation similar to that of the commencement of labor. Similar changes produce disturbances of phonation, deglutition and hearing.

The swelling of the fauces and esophagus may actually prevent swallowing in some cases.

In very severe cases of advanced myxedema, at the approach of death, the enormously swollen tongue tends to fall backward so that the air does not enter the trachea, although the respiratory movements of the thorax continue; the condition being identical with that seen during anesthesia in similar circumstances. After five or six of such false inspirations a spasm of the tongue and pharynx occurs which again allows the entrance of air. Normal respiration is thus reestablished for a time, till again interrupted and restored as before. This condition may be mistaken by an inexperienced observer for a type of Cheyne-Stokes respiration.

Endothelial tissues share in the general feebleness. They are shed prematurely, and such cavities as the gall-bladder and also the urinary bladder are unprotected from the irritating action of their contents. The gall-bladder becomes sensitive, even painful, while the mass of desquamated epithelium may become the nucleus of a calculus. Biliary lithiasis is itself frequent in myxedema, and occurs to a less extent in the milder forms.

The bladder being constantly denuded of its epithelial lining is more than usually sensitive to the irritating action of the urine, and this alone is responsible for many cases of nocturnal enuresis in children. An examination of the urine in these cases shows the presence of a large number of squamous epithelial cells from the bladder. When

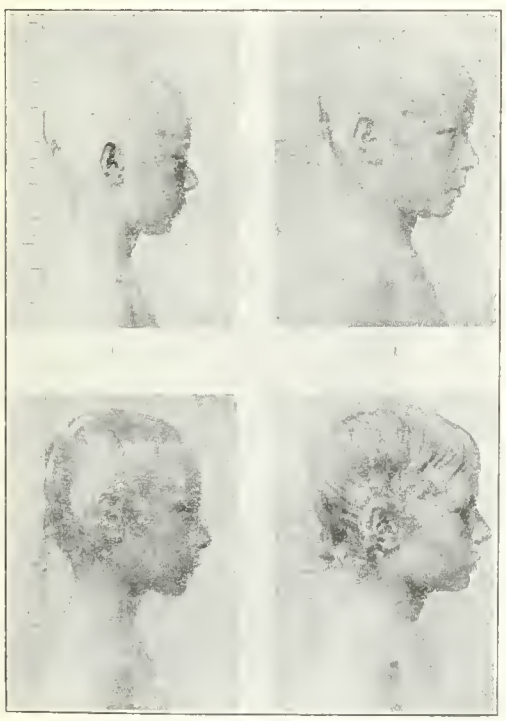

Fig. 4.—Hypothyroidic alopecia; thyroid insufficiency. Influence of thyroid feeding.

closely studied these children present signs of thyroid weakness, and their parents, especially the mother, often exhibit a more or less advanced degree of thyroid defect. As the children grow up the activity of the thyroid gland increases and

these troubles disappear. In girls a trace of them frequently persists as pollakiuria or frequency of micturition.

A most constant symptom of myxedema is a lowering of the temperature. This may be due to

Fig. 5.—Severe myxedema before and after treatment.

the decreased or less active combustion of fats and mucin, or perhaps to the infiltration of the heat-regulating center in the brain. If one suddenly administers large doses of thyroidin to a myxedematous patient, at the time he has a large quantity of infiltration ready to be oxidized, one may observe a considerable elevation of temperature, which may even be mistaken for fever. This is probably due to the ultra-rapid combustion of these accumulated materials.

The lowering of the body temperature is perceived by the patient. It is subject to diurnal variations, being specially noticeable in the afternoon about 4 or 5 o'clock, in the form of violent shivering, starting with the sensation of cold water thrown on the back. These symptoms may be misinterpreted and treated by the useless administration of quinine. In slight myxedema this feeling of cold is present in a lesser degree. The patient is in a state of habitual chilliness, showing itself in women and children by constant coldness of the hands and feet, and the condition known as "dead finger"—pallor, stiffness, and insensibility of one or more digits.

Let us consider the effects of the infiltration on a complex mechanism, such as the cardiorespiratory system, where the different elements we have just studied are associated with one another.

We have to remember the paresis of the cardiac muscle, of the external respiratory muscles, and of the diaphragm; the painful infiltration of the nervous ganglia at the base of the heart, added to the disturbances of its central innervation; the infiltration of the pulmonary tissue, the bronchial mucous membrane of the respiratory tract, and consider the consequences.

The dyspnea presented by some patients suffering from severe myxedema may surpass all description. They can with difficulty climb a short flight of stairs, even with a rest by the way; they arrive in the consulting room absolutely breathless and supporting themselves by the furniture, indicating by signs their inability to speak till they have recovered breath.

In mild cases the oppression is less marked. It may be intermittent and presented only on the occasion of unusual exertion, corresponding to an increased demand on the thyroid gland which is weak already. The condition is then readily mistaken for an attack of asthma, and many so-called asthmatics are certainly suffering from thyroid defect. Certain French writers have reported some unexpected cures of asthma by thyroid extract, and while admitting that the patients presented symptoms of thyroid weakness they persist in describing such cases by the term neuroarthritic. That is not logical; we should rejoice to see the word arthritism, which no one understands and which is so often used as a cloak for ignorance, disappear from the medical vocabulary.

Another example: Consider the gastrointestinal system—the muscular walls are slow and lazy, intestinal secretion scarce, therefrom arises constipation. Microbes find their way to the peritoneum and even kidneys; the peritoneum protects itself by false membranes which in time will grow into bands, bringing on kinks and their consequences. In hypothyroid patients these pericolitic adhesions nearly always exist and are even found in very young children, which is not to be wondered at —hypothyroid disposition being nearly always hereditary.

I would be delighted if my supposition concerning the question of intestinal stasis should prove to be correct. It would perhaps bring into a brighter light still the ideas that Sir Arbuthnot Lane in England and Professor Bainbridge in America have promoted and implanted at the price of a most daring and incessant effort.

Sexual System.—The thyroid gland plays an important part in the development and functional activity of the sexual organs, especially in females. It superintends the growth and general development of the sexual organs. Absolute cretins never come to puberty. In mild forms of thyroid insufficiency the uterus remains infantile and small; menstruation begins late in life. Sometimes the posterior wall of the womb does not grow as quickly as the anterior, and therefrom comes retroflexion. This is by no means a rare condition in very young girls. Profuse menstrual bleeding is often seen in such cases and is attributed to retroflexion. As a matter of fact, the excessive bleeding is caused by the infiltration of the uterine mucous lining, by the defective contractility of uterine muscular cells and by the hemophilic condition of the blood. In thyroid defect hemophilia is quite a classic symptom. Profuse oozing may be brought on by almost a mere scratch.

It is a well-recognized fact that thyroid defi-

Fig. 6.—Severe myxedema before and after treatment.

ciency falls, in nine-tenths of the cases, on females. The reason thereof is easily given: The thyroid has a great influence on menstruation, pregnancy, lactation, and even uterine involution after childbirth. When the thyroid is normally active the

menses are normal; when weak, menorrhagia sets in. The weaker the thyroid the greater the loss of blood. We very often come across these cases of menorrhagia even in very young girls, and we are at a loss to understand the meaning of this

FIG. 7.—Severe myxedema before and after treatment.

distressful condition. We do not know what to do to prevent it. If we can put aside such causes as fibroids and cancer, we will always think of thyroid deficiency.

A large quantity of thyroid stuff is wanted during the menstrual period, and during that time cannot be given to the general keeping up of the body. We often see women who at ordinary times have a decent supply of thyroid secretion run short during the menses, and show then, and then only, the usual signs of thyroid defect. Headaches (migraine) are almost classic symptoms at that time. Many women have muffled voice, which is the result of temporary infiltration of the vocal chords. Extreme lassitude, pains in the back, obstinate constipation, all go along in that line of symptoms.

It is not necessary to dwell on the good effects of thyroid medication under such circumstances. A few doses of thyroid extract will act as a powerful tonic and reduce to a considerable extent the anemic influence of the menses, and reduce considerably the loss of blood.

In pregnancy the thyroid becomes enlarged and throws into the blood an unusually large quantity of secretion, thereby suspending menstruation and protecting the fertilized ovum against the harm which would result from menstrual activity. This action of the thyroid should be remembered in cases where chronic abortion has exhausted all other forms of medication. We may assert that thyroid extract has proved in scores of cases an excellent remedy for otherwise inexplicable sterility. A great many women who have taken thyroid extract with a view to reduce their obesity have been surprised by becoming pregnant in the course of this medication, and this unexpected result is due to the thyroid inhibition of menstruation. After childbirth the maternal system is suddenly relieved; a large amount of thyroid secretion is still in store. Part of it will be given to the muscular and nervous exertion of labor itself and another part goes to the involution of the uterus. The heavy muscular walls of the womb have to degenerate into fat and be oxidized, and this cannot be done without the interference of the thyroid stimulus.

Finally, lactation claims a good deal of thyroid stuff. It has been proven by experiments on animals that thyroid extract works upon the mammary glands and increases the quantity of milk. Women who have a good lactation have also a quick involution of the womb. After weaning, the thyroid gland is now fairly exhausted. Most of mothers grow fat at that time. Menstruation takes advantage of this deficiency and comes back. Thyroid medication may be useful in such cases where lactation is scanty and where menstruation has a tendency to return before the physiological time. This is indeed the only way we have to increase the mammary secretion.

The mucous lining of the vagina is also infiltrated, and under examination gives the impresson of incipient labor. A good many patients have been curetted for hemorrhagic endometritis who were in reality deficient in their thyroid powers.

I acquainted Professor Bainbridge when he was in Antwerp with these facts. Being a gynecologist as well as a surgeon, he said he would make a careful study of hypothyroid menorrhagia. I am glad to say, and he announced it before the Academy, that he is now convinced that this is absolute truth. He has cured a number of cases already with thy-

FIG. 8.—Mild myxedema, showing the loss of hair.

FIG. 9.—The same patient as in Fig. 8 after treatment.

roid feeding, to the astonishment of those who had previously curetted the uterus without relieving the menorrhagia. Much more might be said about thyroid secretion, indeed volumes have been written on the subject. My friend, Dr. Sajous of

Fig. 10.—Mild myxedema—Loss of eyebrows.

Philadelphia, knows about it, and his work on internal secretion has not said all.

The usefulness of thyroid medication is conspicuous in delayed development of the sexual organs, infantile uterus, infantile retroflexion and excessive menstruation. In some cases of sterility and repeated abortion it will prove to be a successful treatment. Slow involution of the uterus after childbirth and wavering lactation will also find here powerful help.

From what we have stated it is evident that the best way to understand mild myxedema is to have a clear conception of the more severe form. The more severe form, when properly treated, gradually progresses through the milder forms to become finally imperceptible even to the most experienced eye. So also, after successful treatment, a myxedematous patient, left to himself, gradually relapses, the milder symptoms being the first

Fig. 11.—Severe myxedema with loss of hair. Before and after treatment.

to return, followed by those of increasing severity, so that the disease reconstructs itself under your eyes. These symptoms of the milder form of the disease are precisely those which should be most clearly impressed upon your memory.

The weakness of the thyroid gland is usually hereditary, and it is rare that one does not find traces of milder defect among the ascending, descending, or collateral relations of a person suffering from well-marked myxedema. One must inquire carefully into the family history; it will be found an inexhaustible source of information regarding symptoms which will render one more familiar with the milder cases of hypothyroidism.

In doubtful cases treatment by thyroidin forms the touchstone whether for mild or severe myxedema. Many persons suffering from the milder forms do not appear stout or swollen, but may even be quite spare in body, the infiltration in such cases predominating in the internal organs. If under small doses of thyroidin such a person loses weight with simultaneous improvement in his general condition, one may assert the existence of insufficient secretion of the gland.

Let us now study some cases of advanced myxedema, and, to facilitate the task, permit me to indicate the course I myself followed at the beginning of my studies on the subject. I confess that when I first found myself in the presence of a case of myxedema I knew nothing about it. I had neglected this part of my medical studies, believing I should never encounter what was then considered a pathological rarity. Myxedema, which meant nothing to me in 1883 when I finished my university course, interested me as little ten years later, when circumstances forced me to concern myself with it, and to recognize it without having suspected its existence.

In 1894, while in attendance at the house of M. X., he confided to me that he was much concerned about the health of his wife. He informed me that she was 64 years of age, had been married at the age of 20, and had had no children. She had been delicate all her life, but recently her condition had been so much worse that he feared a fatal issue was rapidly approaching. In spite of this she absolutely refused to consult a doctor. She was indifferent to all that went on around her, this apathy being combined with an invincible disinclination to all physical exertion. Speech was laborious to her, being slow, faulty, and indistinct, so that usually despairing of making herself understood, she cut short all attempts at conversation. Her only desire was to be left at peace, free from all emotion or anxiety.

Soon after her marriage Mme. X. had a miscarriage. Her menstruation had always been profuse and the intervals between the periods much shortened; the menstrual loss was so great that the blood soaked through the mattress to the floor. She also bled easily after slight injuries, a simple scratch being followed by prolonged oozing. These repeated hemorrhages had produced a state of pronounced anemia shown by the pres-

Fig. 12.—Profile of the patient shown in Fig. 11.

ence of marked pallor and weakness. The hemorrhages were regarded as the original cause of her condition. At the age of 35, while driving in an open carriage Mme. X. was caught in a heavy shower of rain which soaked her to the skin. Following this she took cold and suffered from a well defined attack of acute

articular rheumatism, from which she recovered but had never since been free from pain. From that time her condition was attributed to the rheumatic attack by herself and her friends.

Such was the information given me by the husband, and at his request Mme. X. consented to see me. My

Fig. 13.—Severe myxedema; baldness of the nape

diagnosis was instantaneous—it was evident that Mme. X. was suffering from an attack of Bright's disease in its last stage (Fig. 5). The face was swollen, the eyelids were edematous, leaving only a narrow space between them, the lips were thick, everted, and bluish in color, the speech was slow and drawling, the voice having a strange, deep, croaking tone, while the gait was awkward with slow and indecisive movements. I communicated my opinion to her husband and intimated my fear that a fatal termination was threatening from uremia. M. X. was not surprised and told me that all the doctors previously consulted had been of the same opinion. I then examined the urine and to

Fig. 14.—Same patient as in Fig. 13 after treatment.

my great astonishment it contained only an insignificant quantity of albumin—about 1½ grains to the ounce. There was no renal epithelium present but squamous cells from the bladder were abundant. I was much embarrassed at finding a case of Bright's disease which had reached the stage of threatened uremia practically without change in the urine. Next day I explained to M. X. that the case was somewhat unusual, and asked his permission to keep the patient under observation for ten days in order to make a further examination, to which he willingly agreed.

I could then examine the patient at leisure. The

Fig. 15.—Severe myxedema.

heart presented no appreciable change though the pulse was slow. The kidney region was painless on palpation so far as it was possible to examine it, for Mme. X., while not obese, was short and stout, weighing 204 lb. Her lower limbs did not appear notably swollen and though large were not out of proportion to her body. Her temperature was rather low and she complained of cold although it was the end of May and a large fire made the room uncomfortably warm. The patient told me that she always felt the cold most intensely about 4 o'clock in the afternoon, at which time she felt as if cold water had been poured on her back, causing her actually to shiver. She soon became tired during my examination and even fell asleep while I talked to her, complaining of extreme lassitude and rheumatic pains throughout the whole of her body.

Having discovered all this I had advanced no further than before. That a woman 64 years of age should be sleepy, chilly, easily tired and suffer from rheumatism was neither very extraordinary nor was it pathognomonic. Five days had passed, when chance,—the Providence of doctors,—came to my assistance. M. X.

Fig. 16.—Same patient as in Fig. 15 after treatment.

informed me that he was expecting an early visit from his wife's cousin who suffered from a very troublesome goiter which at times threatened to suffocate her. He also told me that I might be consulted by her and, should alarming symptoms occur, I might even be asked to remove the tumor. Now goiter is a rarity in

Antwerp and for my part I had never seen a single case and was rather worried at the prospect.

My situation was truly awkward, the old lady apparently had Bright's disease but without albuminuria and seemed to be at the point of death without presenting a single positive symptom which I could lay hold

FIG. 17.—Severe myxedeme, before and after treatment.

of;—and then this cousin must needs come from the other end of Austria possessed by the desire to be operated upon for a tumor which she would a hundred times better have had removed in her own country, where they are accustomed to similar exploits.

I returned home in a state of great anxiety and felt a real relief on finding on my table a large parcel containing the treatise on surgery in 8 volumes by Duplay and Reclus which had just been published. I turned to the article on goiter by Broca. Oh, yes! goiter could certainly be removed: it was not easy, but with determination and a score of artery forceps it could be done. Then there were complications—one must not divide the recurrent laryngeal—must guard against hemorrhage and sepsis. And this was not all,—one must beware of removing the whole of the thyroid gland—for this was followed after a short interval by a special cachexia which Kocher had named "Cachexia strumipriva" and Reverdin had called "Post-operative myxedema." This was becoming more and more interesting.

Thus when the patient had escaped from the dangers of the operation, hemorrhage, and sepsis, just when we might expect him to enter upon convalescence, a very strange condition gradually disclosed itself, characterized by the following symptoms:—*lassitude, feebleness, clumsiness, heaviness of the limbs, pain in the arms, legs, neck, and shoulders, swelling of the face and puffiness of the eyelids. The eyes become sunken, the activity of the brain diminished and mental effort dulled.* Then there came an extraordinary

FIG. 18.—Profile view of the same patient shown in Fig. 17.

phase: *"The urine is almost always normal, to the astonishment of the early observers who expected from the appearance of the face to discover albumin.* And again another phrase:—*one of the most remarkable phenomena is a sensation of cold, which is almost constant.*

Truly Mme. X. presented a complete picture of these symptoms. She had the false suggestion of albuminuria without the presence of albumin, and the general swelling of the body. Like the patients operated upon by Kocher, Reverdin, and Bruns, she had the drawling voice, the sluggish attitude of body, the thinned hair

FIG. 19.—Severe myxedema with predominance of rheumatoid pains before treatment.

FIG. 20.—Same patient as shown in Fig. 19, after treatment.

and eyebrows, the swollen mucous membranes, and the difficulty in swallowing. Her tongue appeared too large for her mouth, the floor of which was swollen and raised till it suggested a double ranula. Even her ocular conjunctiva was edematous and prolapsed while her complexion was amber-yellow with patches of red

on the cheeks. She had also the low temperature with subjective sensations of cold—but indeed Mme. X. presented all the symptoms described in post-operative myxedema and if so she must suffer from spontaneous myxedema.

At last my diagnosis was made. On the following day I verified the presence of the hard, nondepressible edema extending over the whole body and some other symptoms which I had not previously recognized. I then informed her husband of what I had discovered and that I was prepared to commence treatment at once. M. X. was too polite to say that he did not believe me, though his face plainly showed his incredulity, but he followed my instructions to the letter.

The result exceeded my hopes. After three weeks treatment the bodily and mental transformation was so complete that she would no longer have been recognized as the same woman (Fig. 5). The edema of the tongue, of the lips, and of the eyelids disappeared as if by enchantment and the face assumed an intelligent expression. The patient then went to the country where the treatment was continued by the local doctor, who gave me valuable assistance. I did not see her again for over two months by which time she had completely recovered, that is to say the absorption of the infiltration had been complete.

Fig. 21.—Severe myxedema, cachectic stage, three days before death.

If you now ask me what we have to learn from this observation as regards mild myxedema, and on what point it helps our knowledge of this condition, I would first direct your attention to the metrorrhagia which is presented by the history of the patient. As a rule thyroid weakness shows itself by the presence of metrorrhagia which is sometimes appalling in its amount. The administration of thyroidin moderates these losses, and if large doses are given one may even completely suppress menstruation, as in the same way complete amenorrhea is not infrequently present in cases of exophthalmic goiter. Women with feeble thyroids conceive readily, but abort as readily in consequence of the onset of profuse bleeding which carries away the fertilized ovum. I do not mean to say that a woman suffering from thyroid weakness cannot go to full term, as from the beginning of pregnancy the thyroid gland undergoes hypertrophy with increase in size and in the amount of its secretion. In fortunate cases this increased activity is maintained throughout pregnancy and forms an effectual protection to the embryo against the menstrual return. Such women tell you that their health is better when pregnant. The increased activity of the gland continues during lactation, and such patients instinctively prolong suckling beyond the physiological period. After weaning, the symptoms of thyroid weakness reappear and certain authors have even discovered in prolonged lactation a cause of myxedema. *Thus when you encounter cases of profuse menstruation in which you can exclude such ordinary causes as fibroids, cancer, or placental remains,* think of possible thyroid defect and search for other symptoms of this condition.

Think of it also in those disheartening cases of repeated abortion, in which the administration of thyroidin will often permit a pregnancy to go to term when all other rational means of treatment have failed.

I would in the second place direct your attention to the rheumatic pains from which this patient suffered. In almost all cases of severe myxedema one finds that the patient at some period of life has passed through an attack of acute articular rheumatism. This affection can itself cause grave disturbances of the thyroid gland, the congestion of which in the course of acute articular rheumatism is a classic symptom. I believe, however, that its influence is usually limited to producing an aggravation of a pre-existing thyroid weakness, thus bringing to light symptoms hitherto unnoticed. The metrorrhagia from which Mme. X. had suffered before the occurrence of her acute rheumatic attack supports this view. The chronic rheumatic or rheumatoid condition is almost always associated with mild myxedema, and its occurrence should be carefully inquired into, especially when metrorrhagia is also present. These pains, which are often complicated by neuralgia, tend to assume a characteristic form and course, to which I will now refer. The most frequent rheumatoid pain experienced in mild myxedema is that affecting the back between the shoulder blades, and is most severe in the morning on rising, after the chilling and inanition of the night. Driven from bed by the pain, these patients rise absolutely worn out, as if they had slept on a hard uneven mattress. The pains subside gradually during the day, owing to the warmth produced by food and exercise, and disappear completely in the evening after a good meal with plenty of wine. Such patients are strongly attracted to the use of alcoholic stimulants.

I have already stated my opinion as to the lowered temperature and the subjective feeling of cold, so I need not insist further on this point. The hard, cold hand of a patient suffering from severe myxedema is very characteristic, and in the milder forms coldness of the extremities is usually present, though to a less degree, as I have already stated.

Among the symptoms presented by Mme. X., one of the more interesting was the special character of the voice and speech. The voice was deep, rough, and croaking, with an indescribable quality which

when once heard could not be forgotten. This symptom is caused by the infiltration of the vocal chords and the pharyngeal mucous membrane, and is present in a less marked degree in milder forms of hypothyroidism. In women with feeble thyroids the voice is slightly hollow or muffled. Sometimes this is only occasionally present, as during menstruation, when a considerable part of the thyroid resources is employed in the inhibition of the menstrual function. We will not consider further the case of Mme. X., though interesting from the standpoint of our subject, but will bear in mind as leading symptoms the *metrorrhagia*, the *recurring abortions*, the *rheumatoid pains*, the *feeling of chilliness*, *and the alteration of the voice.*

After my attendance on Mme. X., I reproached myself for having so long neglected to inform myself as to the diseased conditions of the thyroid gland. During my ten years of practice I must have already met with these cases of apparent Bright's disease; I had treated them, and they had disappeared and been forgotten. Surely I had heard somewhere a voice similar to that of Mme. X., but when? and where? On racking my brains, I remembered that one day I had been summoned as an expert before the Civil Pensions Commission, the administrative body to which the servants of the State apply when on account of infirmity they wish to claim their pension before the retiring age or when it is necessary to retire them. It decides in accordance with the advice of the medical experts.

FIG. 22.—Myxedema, severe form, before and after treatment.

A professor of solfeggio in the Antwerp Conservatoire had appeared before us. His condition was so lamentable, so profoundly cachectic, that my colleague and I requested the President to send some one home with him lest he should fall in the street. The strange, hoarse, croaking voice of this man whose occupation was the teaching of singing to children, was so irresistibly comic that commissioners and doctors alike had great difficulty in keeping their gravity. The medical examination did not take long and the verdict was explicit—Bright's disease in its last stage with uremia, and he was at once retired on pension.

I searched for and found the singing master who was still alive, and whom I now recognized to be suffering from myxedema. I show here his photograph before and after treatment (Fig. 6). I informed the Minister of the error, who sharply rebuked the Commission for a mistake made through no fault of theirs. The board then had the patient examined afresh by other doctors, who discovered nothing wrong with him as he no longer presented the least sign of myxedema. The proposal to retire him was withdrawn, and his voice having now recovered, he was able to resume his class with a brilliancy to which he had been long a stranger. He was at this time 55 years of age. Before treatment was begun his whole face was swollen, especially the eyelids, the space between which was reduced to a mere slit. He also suffered from rheumatic pains, a constant feeling of cold, and continual dyspnea. The skin was dry, thin, and scaly, the epidermis covered with fine lozenge-shaped wrinkles. The whole body was heavy, clumsy, and infiltrated with a firm resistant edema. He complained of invincible somnolence, depression, and weariness of life. The infiltration was rapidly absorbed under treatment, his weight falling from 169 lb. to 136 lb. in two months, at the end of which period the second photograph was taken.

Here for the first time dyspnea appears as a leading symptom of myxedema. The patient had suffered from it for a long time, and in my former notes of his condition I found it occupied an important place. His walk was slow and difficult, and he required to support himself by the furniture, making signs that he could not speak for want of breath. In mild myxedema this breathlessness is constantly present, though to a less degree, only showing itself on walking rapidly or uphill, and is usually accompanied by palpitation. Sometimes the breathlessness is intermittent, like the insufficiency of the thyroid secretion on which it depends, and is then liable to be mistaken for an attack of asthma.

The gratitude of this singing master was all the greater that he had been restored to his duties and escaped the misery of a premature pension. He told me that one of his friends, a police agent, who had been put upon the retired list ten years before, suffered from the same condition as himself. This was rather too much—to have myxedema diagnosed by a patient who had only just recovered from the disease.

I called on the police agent whose appearance before and after treatment is shown in the photographs (Fig. 7). He was suffering from very advanced myxedema and though only 42 he appeared much older. The photograph shows the degree of cachexia at which he had arrived. His whole face was infiltrated, the eyelids being so swollen that the eyes could be opened only with the greatest difficulty, while the thickened lips resembled those of a negro. The complexion was amber yellow with bright red patches on the cheeks. The trophic changes in the hair were striking, the forehead presented a band of brown pigmentation and there were similar marks on each side of the neck. The head was too heavy for the infiltrated muscles and

ligaments of the neck so that it fell forward and the patient could raise it only by throwing the trunk backwards. He complained of rheumatism and a perpetual feeling of cold, huddling himself night and day under thick bedclothes. The breath was offensive, the teeth bad, the gums red and inflamed. Speech was much

FIG. 23.—The patient shown in Fig. 2 after 14 years of treatment.

impaired. On replying to a question he opened his mouth widely, so that the motions of his tongue could be plainly seen although he uttered no sound, and it was only after a lengthy effort that the words were slowly formed. His weight was 152 lb. of which he lost 22 lb. under treatment with the simultaneous improvement of all his symptoms. The loss of weight in this case amounted to 18, 28, and even 35 ounces a day. His hair grew again rapidly, muscular contractility was regained so that he could again raise his head, and he was delighted to find his self-confidence return, complete recovery being attained in about two months.

This case directs our attention to the trophic changes of the hair, teeth, and gums. In the milder type of myxedema the hair may also be shed early, though more frequently it becomes prematurely grey. The destruction of the teeth and the chronic alteration of the gums is also observed, though to a less extent.

Whatever the type of myxedema, the baldness very constantly presents a special distribution, the hair being first shed in the frontal region, then on

FIG. 24.—Mild myxedema in the mother of the patient pictured in Figs. 2 and 23.

the nape of the neck, giving the appearance which is well shown in Figs 8 and 9. The loss of the hair in the eyebrows is early and constant, even in mild myxedema, and has been called the eyebrow sign. It is not so easily concealed as the baldness of the scalp, and it gives to the patient's face an air of perpetual astonishment.

Fig. 10 is the portrait of a woman aged 24 who had suffered from uterine hemorrhage since her confinement, four months previously, for which she had been packed and curetted several times. The absence of the eyebrows is striking, and though the frontal baldness had been artfully concealed, she at once suggested to me a case of insufficient thyroid secretion. She suffered much from migraine and also from occipital headaches; she was always cold, while her menses were always very profuse. Under thyroid treatment the hemorrhage ceased in a fortnight.

A very interesting case of myxedema is shown in figures 11 and 12. There was marked loss of hair which in addition to the usual situations had affected the sagittal line, but the baldness was concealed by the presence of black crusts which covered the whole scalp, the eyebrows were also markedly affected. This patient might be classed as an advanced case of myxedema and the result of treatment was very striking. She had always been tired, constipated, and somnolent. She was never free from rheumatic pains and became breathless on the slighest exertion. Her face was infiltrated, the eyelids and lips being specially swollen. Under thyroid extract she rapidly lost 22 lb. in weight and after four months treatment, was completely changed both morally and physically, having regained courage, strength, and cheerfulness. She even became coquettish and would not believe that her appearance had been as in the first photograph.

The patient shown in Figs. 13 and 14 is a good example of the effects of thyroid weakness on the hair and eyebrows. She was only 39 years of age, but

FIG. 25.—Mild myxedema, before and after treatment.

appeared much older. The face was swollen, amber yellow in color, with patches of red on the cheeks. The trophic changes had chiefly affected the hair and teeth, the nape of the neck being almost bald. She complained of a constant sensation of cold, obstinate constipation, and pains all over the body, which she attributed to rheumatism. She presented also the drawling voice with its characteristic intonation. Her weight was 154 lb., of which she lost 22 lb. in the course of treatment.

The patient presented in Figs. 15 and 16 was 42 years of age. Fourteen years before, as the result of a chill, she suffered from swelling of the hands and feet with albuminuria. She was treated for Bright's disease, but did not recover her health, dragging on in a weak, exhausted, somnolent condition, with pains in all her limbs. Becoming pregnant she suddenly improved considerably, due to the stimulation of the thyroid gland by her condition. This improvement lasted throughout pregnancy and was maintained during lactation, although she nursed her infant for two years. After weaning him she gradually relapsed into her previous condition, again becoming apathetic and depressed while the rheumatic pains returned with increased severity. The eyebrows were very thin, the features swollen, while the pale yellow complexion recalled that usually associated with albuminuria. She suffered from constipation and headache, her teeth were decayed, and she presented attacks of shivering during the evening which were attributed to fever. All these symptoms improved under treatment, her weight at the same time falling from 143 to 138 lb.

The patient shown in Figs. 17 and 18 was only 39 years of age. He was a cigar maker, who had been

unable to work for six years, owing to his fingers having become stiff and clumsy. He had taken to drink and he and his family had fallen into extreme poverty. He was positively ugly, and the boys of the district, who knew him under the name of Ravachol, followed him on the street. I literally picked him out

FIG. 26.—Severe myxedema before treatment.

of the gutter and kept him under observation for a week before commencing treatment. His appearance is well shown in the illustrations. He complained of pain in the spine, a constant feeling of cold and insuperable fatigue, and was melancholic, depressed, and extremely miserable. His hair was unaffected, except in the occipital region, which was bald. During the week before treatment was commenced he excreted on an average 323.4 grains of urea per day, which increased under thyroidin to an average of 477.4 grains per day, during the first week, with a further increase during the second week to 677.6 grains per day. In

FIG. 27.—The same patient as in Fig. 26, after two months' treatment.

consequence of the absorption of the infiltration his weight fell from 167 lb. to 138 lb. His urine contained an extraordinary number of spermatozoa, this symptom persisting for a whole month, when it suddenly ceased. He rapidly recovered as shown by the illustration, and he not only regained his health but also his self-confidence, so that he resumed his work, at which he was expert, and after some months sailed for America in quest of a better situation. He obtained work at once, and is now himself an employer, and has made money. Every two or three years he returns to Europe to express his gratitude to me.

FIG. 28.—Severe myxedema.

Soon after the cure of the singing master and the police agent I remembered that at the beginning of my career I had treated a woman of whose peculiar voice I was reminded by that of these two patients. She had left town, but at last I discovered her. In those days she had suffered from rheumatism involving all the body, the muscles being stiff, hard, and painful. The joints were also swollen, the gait stiff and awkward, while the pains in the back were very severe. I had formerly treated her by every

FIG. 29.—The same patient as in Fig. 28, after treatment.

means I could think of, without benefit. On her reappearance I found that she was really suffering from myxedema—as you will see by the photographs before and after treatment (Figs. 19 and 20). The puffiness of the face, the swelling of the lips, espe-

cially the lower one, the loss of the hair of the scalp and eyebrows, the redness of the cheeks on a yellow skin, the drawling, croaking voice, the dry wrinkled skin, and the desquamation of the scalp left no doubt as to the diagnosis. Under thyroid

Fig. 30.—Mild myxedema with atrophy of the optic nerves.

treatment the infiltration rapidly disappeared. The general pain and stiffness also disappeared steadily, though slowly, along with marked breathlessness, to which she had always been subject, and which I had formerly attributed partly to obesity and partly to pulmonary emphysema. Finally all these symptoms were completely abolished, but on the patient ceasing treatment the pains gradually returned, to cease again on the administration of thyroidin. This woman had suffered from these rheumatic symptoms for so many years that she had become resigned to them, and sought advice only when the pain in the back or the swelling in the wrists or knees became unusually severe. *The pain was then, as later, simply a manifestation of defective thyroid secretion.*

Let me now record a case illustrating the disorders of the liver associated with defect in the thyroid gland. The patient shown in Fig. 21 was a women suffering from myxedema in its last stage. She died three days after admission to my ward without it being possible to begin thyroid treatment. On post-mortem examination the gall-bladder was found much enlarged, distended to the bursting point, with marked thinning at its upper pole. It contained a large gallstone, which permitted the entrance but not the escape of the bile. I was much impressed by this observation, and later in cases of myxedema, whether mild or severe, I examined for tenderness of the liver and especially of the gall-bladder. Very frequently, not to say always, a painful point was found in this region, which disappeared during treatment. Although the presence of a calculus in the gall-bladder is a common occurrence in the post-mortem room, I have dwelt on it and shown this photograph in order to emphasize the frequent presence of disorders of the liver in myxedema, of whatever type. In this affection one should always think of congestion of the liver and the possible presence of calculi or biliary sand in the gall-bladder. The amber yellow coloration of the skin, so characteristic of myxedema, is only an attenuated jaundice and depends on biliary disturbances.

Fig. 22 is that of a woman aged 40 years of age, suffering from well-marked myxedema. Her father, who was dead, had suffered from rheumatism and albuminuria. She had six children; the eldest daughter was subject to metrorrhagia, while two of the sons had suffered very severely from acute articular rheumatism. Her appetite had completely gone, she suffered from menorrhagia, with headaches and frequent attacks of shivering. Her temperature taken in the mouth was only 96.2 F. There was great swelling of the face, but the hair was well preserved and the teeth in good condition. She suffered from melancholia and apathy with difficulty of thought, speech, and action. After six weeks' treatment at the Institute she was discharged so changed in appearance that she would not have been recognized. Since then she had continued her treatment, but only very irregularly. When she neglected it too long the first symptoms of relapse were a feeling of weight at the stomach, difficulty in stooping, tenderness over the liver, and a distaste for meat. After an unusually long period of neglected treatment she sent for me in haste one night and was found suffering from biliary colic. The urgent symptoms yielded to oil and morphine and later under thyroidin she made a complete recovery.

I have said that an excellent means of becoming acquainted with the slighter degrees of myxedema is to study the morbid characteristics of the ascending, descending, or collateral relations of patients suffering from the more severe type, the weakness of the thyroid gland being essentially hereditary. I have shown in Fig. 2 four photographs of a child who suffered from severe myxedema, and presented marked delay in her physical and intellectual development. When first brought to me in November, 1896, she was 8 years of age, and she measured only 2 ft. 10 in. in height, instead of 3 ft. 10 in., the normal average for her age, though she was comparatively heavy, her weight being 33 pounds. The expression of the face was that of well-marked myxedema; the face itself was swollen with the characteristic red cheeks on an amber yellow skin.

Fig. 31.—Same patient as in Fig. 30, after treatment.

The dystrophy had not involved all the tissues to the same extent, those of epidermic origin being relatively intact. The hair was black and thick, the eyebrows were well marked, while the teeth were healthy, an exceptional event in myxedema. The

bones, on the other hand, were severely affected, the femora were curved, the tibiæ and fibulæ showed advanced signs of rickets, and the feet were short and flat. The belly was large—a characteristic of this affection—and presented an umbilical hernia.

Fig. 32.—M. A., severe myxedema; before treatment.

The false ribs had been carried outwards by the distention of the abdomen—a change more apparent in the second photograph, where the belly has been reduced by a year's treatment. Her intelligence was but slightly developed. Her temperature was very low, even in summer, and in winter it became extremely so, there being great difficulty in keeping her warm. She throve badly, and was extremely constipated. There could be no doubt as to the

Fig. 33.—M. A. after two months' treatment

cause of the condition—a congenital weakness of the thyroid gland.

The patient's mother had suffered from several severe attacks of malarial fever in the course of her pregnancy, and had been obliged to leave the low-lying village where she lived and come into town for her confinement. Four years previously, before she lived in this low-lying district, she had borne a son, now 12 years of age, who was slender and delicate. A second child had died of some abdominal condition at the age of five months, the third being

Fig. 34.—M. A. after 14 months' treatment.

the patient with whom we are now concerned.

I have often observed that for the production of a severe case of congenital myxedema the association of at least two grave defects in the parents is necessary, as, for example, the coexistence of syphilis and tuberculosis; gout or diabetes, complicated with tuberculosis or syphilis; or, again, the coincidence of alcoholism and syphilis. The mother was therefore carefully examined to discover the

Fig. 35.—Sister of M. A.—Myxedema.

defect which, joined to malaria, had produced such a complete degeneration in the fetus. She suffered from severe migraine, was very constipated, her liver and gall-bladder were tender, and her menstrual loss was excessive. She also complained of transient rheumatoid pains in her muscles, which

became aggravated during the cold season. She was dull, depressed, almost melancholic, and presented a low temperature, frequent breathlessness and palpitation. Her complexion was pale yellow, like that of the child. Vertigo, tinnitus, and muscæ volitantes were also present.

The clinical picture was that of the simpler forms of thyroid defect. Without being myxedematous she evidently suffered from thyroid weakness. The malarial poison had done the rest, and the mother, unable to furnish the fetus with the necessary amount of thyroid secretion, gave birth to a cretin.

The little patient quickly responded to treatment by thyroidin. After a year her appearance had much improved, as seen in the second photograph (Fig. 2*b*). At the beginning of treatment the thyroid extract appeared to disagree with the patient, causing vomiting in the morning, before breakfast, but in spite of this its administration was continued. During the first year she gained 5½ inches in height, while the rachitic deformities greatly improved but did not entirely disappear. The distended abdomen assumed more natural proportions, the umbilical ring closed, and the neck became more slender. The expression of her face became more inquiring and thoughtful. Her progress during the second year was less satisfactory, as she unfortunately suffered severely from whooping-cough, which lasted five months. The increase in height amounted to only 2¼ in., but all traces of rickets had disappeared from the limbs. The third photograph (*c*) shows her appearance at the end of the second year.

The action of infectious diseases on the activity of the thyroid gland has been well known since the work of Marcel Garnier.[5] He states in connection with a case of whooping-cough which proved fatal by bronchopneumonia: "The thyroid gland was completely transformed. (on post-mortem examination). The coloring matter was almost entirely absent; the vesicles were empty; the thyroid cells, more or less raised towards the interior of the cavity, did not fill it, and there was no cellular proliferation, so that the thyroid tissue appeared like a fine network between the meshes of the connective tissue, which were closer than usual. There was in this case an arrest of the colloid secretion, a state of *athyroidism*." Garnier attributes these lesions to the bronchopneumonia rather than to the whooping-cough, but we may remark that whooping-cough is almost constantly complicated by bronchopneumonia, and it certainly was so in the case of our little patient. One is not then astonished at the slight progress made during the second year, and it is worthy of note that whooping-cough showed itself able to lower the secretory activity, even in this child, apparently destitute of an active thyroid gland. I believe that however degenerate it may be, the thyroid gland, even in the most confirmed cretinism, never loses entirely its secretory power, as the complete absence of thyroid secretion from the blood causes death in a short time.

In the course of the second year the parents became much alarmed at the appearance of a defect in speech, which they attributed to the treatment. I have seen several similar cases in analogous circumstances. The child had great difficulty in articulation, the first syllable being specially hard to utter, so that she panted, gasped, and twisted herself about. Soon, however, this disturbance ceased spontaneously. During the third year the patient gained 2½ inches in height.

The progress in the fourth year was also unsatisfactory, the treatment being irregularly followed and even interrupted for some months. There was, however, a gain of 1½ inches. After a serious admonition the parents became more attentive, and in the course of the fifth year the child's growth showed a distinct improvement, the increase in height amounting to 3½ inches. The fourth photograph (Fig. 2*d*) shows the patient as she appeared after five completed years of thyroid treatment. During that period she had gained 15½ inches in height, her lower limbs were straight and well formed, and the most trained eye could no longer detect the slightest indication of thyroid defect.

This case confirms the ideas which we have long expressed on the etiological unity of several morbid states which have been attributed to very diverse causes. Such conditions as infantile obesity, rickets, the slender type of infantilism, anangioplasia, chondrodystrophy, myxedema, the arrested growth in congenital syphilis, the arrest and delay of growth associated with alcoholism, tobacco poisoning, malaria, and tuberculosis, are all due in their last analysis to the same cause—a lesion of the thyroid gland. Syphilis, tuberculosis, alcoholism, chronic malnutrition, and consanguineous marriages alike deal their first blow at the thyroid gland and alter its secretion in various directions. Does not the perfect recovery from the rachitic changes in our little patient show us that this condition is due to an alteration in the thyroid gland? Thyroid extract is essentially a specific and can benefit only the lesions which come within its sphere of influence.

The different morbid influences which we have just enumerated do not all affect the thyroid secretion in the same manner. This secretion is very complex in its composition, containing nucleins associated with phosphorus, iodine (Baumann), arsenic (A. Gautier), and even bromine. The thyroid gland is liable to injury from several directions, and from this results the great variety of trophic disorders which are the echo of its impairment.

To return to the patient, I may state that she continued to grow till 21 years of age, when she measured 4 feet 9 inches in height. Her appearance at the age of 24 is shown in Fig. 23.

Her mother's portrait is shown in Fig. 24, her hair is silvery white, but she now finds herself healthier than fourteen years ago. Since the menopause, the thyroid secretion, which during her reproductive life was devoted to the inhibition of menstruation is now fully available for the general nutrition of the body. She still suffers, however, from breathlessness and rheumatic pains, and when these symptoms become troublesome she takes thyroidin for a time with beneficial effect.

Let us now take an example of mild myxedema occurring in a descendant of a patient presenting a more severe type of myxedema.

The patient shown in Fig. 25 was the daughter of the singing master whose case I have previously described. The woman was 40 years of age. At all times her menstruation had been profuse and exhausting and she suffered much from migraine and dullness in the head, while her hair had come out freely. When closely examined her face presented a slight degree of swelling, she was tired, worn out, somnolent, with an urgent desire to sleep. At the time she complained of sciatic pains in the left leg. Her hands were large, cold, bluish red in color and were covered with chilblains in winter. Under very small doses of thyroidin the swelling of the face disappeared, and the other

symptoms ceased, including the shooting pains in the left sciatic. This case forms a good example of mild myxedema.

Finally, let me give an example where the study of the collateral relations of the patient has been of great value.

The venerable ecclesiastic shown in Figs. 26 and 27 suffered from well-marked myxedema. He was the priest of a parish in the neighborhood of Antwerp, and having visited his church, which was of archeological interest, I heard him preach. He stood by the steps of the altar painfully supporting himself with both hands on the communion rail. His speech was so defective that I could not understand a word of his discourse. Then he mounted the steps of the altar, very slowly, and with great difficulty, leaning on the shoulder of the server. There was no doubt as to the diagnosis, he was suffering from well-marked myxedema. I had the satisfaction of quickly restoring him to health, as may be seen in the photograph. This patient, as you may imagine, had been previously treated in various ways in the course of a disease which had lasted ten years. He was much troubled by great thickening of the nasal mucous membrane, for which he consulted a specialist, who nimbly removed a portion of his turbinals, at the price of an alarming hemorrhage. Myxedematous patients are very hemophilic. The operation had no beneficial result for the patient.

I inquired into the state of health of his brothers and sisters. One of the latter lived with him, she was very thin and had a pronounced nasal voice with marked hypertrophy of the mucous membrane of the nose. This was in her the only symptom of thyroid defect. Another sister was married and presented the appearance shown in Fig. 28. She was as myxedematous as her brother the abbé. Under treatment she quickly and completely recovered her health. (Fig. 29.) But this was not all.

The abbé had a brother aged 54, who for ten years had suffered from an obscure condition characterized by weakness, anemia, and progressive exhaustion (Fig. 30). Along with the loss of strength his vision had gradually failed which had been attributed by well-known specialists to white atrophy of the optic nerves. Three years before, on his return from an exhausting journey, he suffered severely from headache, then suddenly collapsed and became unconscious with complete loss of motion and sensation. This state of coma lasted three days and on recovery he remembered nothing that had taken place, but presented no loss of functional power. He continued to suffer from weakness and exhaustion and his eyesight became steadily worse, so that when I saw him two years later he was almost blind. White atrophy of the optic nerves has been recorded several times in the course of myxedema, but I believe that this is purely a coincidence, and that there is no causal relation between these two affections. If the alteration of the optic nerves was caused by the specific myxedematous infiltration, vision would return under the influence of thyroid treatment, as we have seen that the most pronounced changes of the nervous system due to this cause are capable of complete restoration. The attack of coma which the patient had presented had placed his medical attendants in a serious difficulty. As there was no history of syphilis, the diagnosis appeared to lie between a tumor, hemorrhage, and embolism of the brain, serous apoplexy being excluded by the absence of albuminuria. I confess, if I had not previously seen the abbé and his sister, I would not have suspected thyroid weakness in this case, but once my attention was directed to this possibility it was easy to confirm the diagnosis. The low temperature, the yellowish pallor and slight swelling of the face, the fine and scanty beard, the breathlessness, and extreme weakness all pointed to this conclusion. Even the attack of coma, hitherto so difficult to explain, fitted in with this opinion in a very simple manner. As the result of an harassing journey there was produced an abnormal exhaustion of the resources of the thyroid gland in a patient in whom they were already very restricted. This had caused a severe and sudden infiltration of the nervous centers, producing an attack of coma. The immobility secured by the unconscious condition of the patient permitted the recovery of the secretory activity of the gland, and the consequent absorption of the infiltration, so that the coma passed off without leaving any paralysis or loss of function. On being submitted to thyroid treatment, this man regained strength, color and self-confidence, his appearance being shown in Fig. 31. The anemia completely disappeared, but his eyesight did not improve nor could it be expected to do so.

A last example showing the utility of an inquiry into the family history is the case of M. A., whose photograph is shown in Figs. 32 to 34. This is the most severe case of myxedema which I have yet met with, and also that which I have most closely studied and the treatment of which I followed from day to day. When I first saw him, the patient was 63 years of age. As you see by his photograph, he was much infiltrated and weighed 221 lb., although he ate very little, having a distaste for all food, especially meat. He suffered much from breathlessness and was incapable of the slightest exertion. Three years previously he had had an attack of epistaxis, which lasted five days and threatened to prove fatal, when the bleeding was arrested by an injection of antidiphtheritic serum. Soon after this he became suddenly comatose for a period of eight hours. As he had long been known to suffer from albuminuria, and had been treated for Bright's disease, the coma and epistaxis were naturally attributed to the renal affection and regarded as signs of uremia, while the dyspnea, intellectual dullness, headaches, vertigo, and noises in the ears were believed to be due to the same cause. This interpretation must be admitted to be both scientific and logical. He also suffered from nocturnal incontinence of urine which caused him great distress. He rapidly improved under treatment, his appearance after two months being shown in Fig. 34. At this stage he was still weak and his features were somewhat haggard, but the fierce expression they had assumed was quite misleading as the man was amiability itself. His appearance after fourteen months' treatment is shown in Fig. 34. He has become a little stouter, but is in complete possession of all his faculties and his face well reflects his character as he shows extraordinary energy in the management of his affairs. His recovery was absolutely complete. Some idea of the extent of the myxedematous infiltration may be obtained by a study of the loss of weight presented by this patient. His original weight was 221 lb., which was reduced in the course of two months' treatment to 163 lb. He thus lost 48 lb., or about 23 per cent. of his total weight in sixty days, being at the average rate of nearly 13 ounces a day.

I naturally inquired into the family history and found that about ten years previously the patient's sister had died in a state of coma following great fatigue on the occasion of a removal. She had formerly had an attack of coma and had for some years presented albuminuria and been treated for Bright's disease. A photograph of this sister is reproduced in Fig. 35. You will observe that it has been carefully retouched in order to supply the absence of the eyebrows and that the photographer has unsuccessfully endeavored to reduce the swelling of the face and neck. It is certain that this woman suffered from myxedema and that the apparent Bright's disease, including the fatal attack of coma was due to myxedematous infiltration. Suitable treatment might have saved her as it saved her brother.

I need not further multiply examples, but may sum up by saying:

When you encounter the association of one or more of the following symptoms: Trophic changes in hair, eyebrows, eyelashes, teeth, or gums; an habitual chilliness, biliary disturbances with lithiasis, dyspnea with asthmatic attacks; menorrhagia, recurring abortion, hemophilia; melancholia, depression, weariness of life, migraine, vertigo, sudden loss of consciousness, noises in the ears; somnolence, rheumatoid changes in the muscles, ligaments, or aponeuroses; nocturnal incontinence of urine, pollakiuria, loss of appetite and obstinate constipation—think of a possible deficiency of the thyroid secretion.

Treatment.—I will conclude with some practical indications as to treatment. The theory of thyroid defect which I have submitted to you is based on the undoubted existence of an infiltration, the amount of which varies with the degree of deficiency, but which is always present. This theory agrees with all the known facts and is strongly supported by the complete restoration of the body as the result of treatment. There is no destruction of even the most delicate tissues, since all of them are capable of resuming their functions after the administration of thyroidin. This theory also assists us in judging the progress of the patient and explains the various incidents which may be produced in the course of treatment. *Thus, the too rapid absorption of the infiltration from the muscular, nervous, connective, or osseous tissue causes painful phenomena exactly similar to, but more acute than, those experienced during the primary distention.* These pains are easily explained by the too sudden shrinking of the walls of the cells, and perhaps also by the increased oxidation of their contents. Too intensive a treatment produces violent headaches, neuralgia, anginiform cardiac symptoms which are apt to alarm both the patient and the doctor. Very acute rheumatoid pains also develop in the muscles, tendons, and joints, especially affecting the anterior muscles of the leg, the extensor tendons of the foot, and the joints of the toes. I have already spoken of the rise in temperature which occurs in the course of too rapid treatment.

In the treatment of myxedema, whether mild or severe, let us have the courage to be patient and proceed slowly, as it is unnecessary to cause the absorption of more than 3½ to 5 ounces of infiltration per day.

In adults a dose of 5 grains of thyroidin, corresponding to an English tabloid of thyroid extract, is quite sufficient, and even this small dose often provokes disagreeable symptoms in connection with the heart, muscles, and joints. Absorption of infiltration should be controlled by daily weighing of the patient. It is found that children tolerate thyroidin better than adults.

This fundamental treatment should be assisted by the observation of certain dietetic rules. Wine, beer, alcohol in every form, and also tobacco, should be prohibited, because these toxic agents diminish the activity of the thyroid gland, and it is important to spare that of the patient, however much degenerated it may be.

Complete rest in bed is also useful during the first period of treatment, because when in bed the thyroid secretion of the patient is not expended in useless muscular action. Certain forms of mild thyroid defect derive benefit from the administration of small doses of arsenic, iodine, or bromine, because these substances form part of the thyroid secretion. Arsenic is of value in the forms associated with migraine, while a combination of iodine and bromine benefits the cases of incontinence of urine. A few doses of an active purgative may be required to clear the viscera when loaded after long-continued constipation.

I need hardly say that I absolutely forbid all cold bathing, but hot baths on the contrary are both useful and pleasant to the patient.

When the infiltration has been absorbed, that is to say, when the patient no longer loses weight, one must endeavor to fix the dose of thyroidin necessary to maintain him in health. This varies from 1 to 6 tabloids a week, the amount being slightly increased in winter and decreased in summer. When once the patient is cured one should not be alarmed to see him increase slightly in weight, as with the better assimilation an increase of stoutness is to be expected.

Finally, it may happen that a case of myxedema comes under observation so late that treatment seems hopeless, the patient having sunk into a state of complete coma, and death seems imminent. I recently saw a woman in whom at times false respiratory movements occurred, giving the impression of Cheyne-Stokes breathing in a dying person. For several days two nurses took turns at her bedside in order to support her chin. A metal tube was inserted between her teeth and connected with a supply of ogygen, and at the same time thyroidin was administered by hypodermic injection. The symptoms rapidly improved, the periods of suspended respiration became less frequent, the somnolence disappeared, and the temperature rose considerably—an evident sign of the oxidation of the infiltration. I consider this patient was saved by the hypodermic injections of thyroidin.

In a case of prolonged coma one would be justified in performing lumbar puncture for the relief of the nervous centers.

I have now sketched the leading features of thyroid defect in its various degrees. I have not been able even to enter on a number of interesting points, but I have said enough to enable you to observe around you facts which you have perhaps hitherto not suspected. It is for your to complete these notions, and in order to do so it suffices to think of them. Trousseau has well said that the life of a physician should be a long meditation.

Just as we search all our patients for tuberculosis, syphilis, alcoholism, a day will come when a systematic examination will also be made to ascertain their thyroid powers and defects. The question of the internal secretions is coming more and more to the foreground. Innumerable possibilities may arise from it. I must now conclude and thank you for the attention and time you have so liberally given me.

INTRATRACHEAL INSUFFLATION.*

By BENJAMIN MERRITT RICKETTS, M.D.,
CINCINNATI, O.

As early as the middle of the sixteenth century Vesalius I. recognized the possibility of aerating the blood, after the chest had been opened, by passing a continuous current of air through the lungs; while in 1667 Hook read before the Royal Society a paper entitled, "An Account of an Experiment Made by Mr. Hook by Preserving Animals Alive by Blowing Through Their Lungs with Bellows."

*A lecture delivered at the New York Polyclinic Medical School and Hospital, April 16, 1914.

In his experiment, Hook, having laid open the entire thorax of a dog and removed the pericardium, sustained the animal's life, first by reciprocal inflation and deflation of the lungs, in imitation of normal respiration, and then by means of a constant current of fresh air under such pressure that all respiratory movements of the lungs themselves were suspended. Both methods were successful in continuing animation and the pulmonary circulation.

While mechanical respiration remained a valuable adjunct of laboratory experiment for almost 250 years, its failure as a human resuscitative measure in the practice of such surgeons as LeRoy of France, and Monroe and Dalrymple of England, forced the scientist, John Erichson, in 1845 to conclude that, "In spite of all the improvement and modifications of the technique and the methods of inflation by bellows, mechanical respiration never again came into favor and was speedily forgotten when the postural methods came into use."

Marshall Hall was especially severe in his condemnation of forced mechanical respiration by means of bellows, and until 1887 the postural resuscitative methods of Hall, Sylvester, Schäfer, and Howard were extensively employed.

On July 23, 1887, Dr. George Edward Fell of Buffalo, N. Y., after all the postural methods of resuscitation had been tried and failed, by means of forced respiration saved the life of a patient who had taken twenty grains of morphine and some chloral hydrate, even after the pupils had dilated in the last stage of asphyxia. Within about three months following, Prof. Dr. Boehm of the Allgemeines Krankenhaus in Vienna saved the life of Dr. Langer by the same method.

Other successful cases of a similar character followed, and established a new epoch of artificial respiration. In practice Dr. Fell used an especially devised face mask and a trachectomy tube, and lated an intubation tube, the invention of Dr. O'Dwyer, connected to a single bellows and provided with a coronet piston exit valve, by the manipulation of which inflation and deflation of the lungs could be made to duplicate normal breathing. In one instance, the case of Dr. Williams, reciprocal respiration was continued intermittently during four days, with recovery of the patient, and without any untoward pulmonary laryngeal or systemic complications.

It was through the incentive given to artificial respiration by the introduction of Fell's method of "forced respiration," and his adaptation of etherization to the technique, that the surgery of the thorax, through its utilization became a possibility. F. W. Parham of New Orleans was the first to successfully remove a sarcomatous growth from the walls of the thorax, using "forced respiration anesthesia" by the Fell-O'Dwyer method, for purposes of the narcosis and combating pneumothorax. The operation was performed under reciprocal breathing, and the chest walls were closed with the lungs fully inflated. Complete recovery of the patient ensued.

About 1896 the French surgeon, Tuffier, in association with Hallion, after exhaustive intrathoracic experimentation under continuous insufflation, concluded that, "the success of this method on animals justified its use in man." In 1902 Matas turned his attention to a solution of the surgical problems involved in pneumothorax.

Kuhn of Cassel, who had made intubation a specialty since 1895, in 1905 came out with a positive differential method for compensating pneumothorax, based on insufflation by intubation. He at first closed the mouth tight, but in 1908 improved his previous technique by introducing two tubes in one, a narrow tube for inbound compressed air and a wider one for the exhaust. After many experiments on the human being, Kuhn found it advisable to keep the tube out of the trachea, and to stop it just below the larynx. While Kuhn demonstrated the pulmonary application of anesthesia by intubation to Czerny of Heidelberg, Trendelenburg of Leipsic, Angerer of Munich, and Lotsch of Berlin visiting each of these surgeons personally, nevertheless the method was not favorably received for use in intrathoracic surgery on the human subject.

In 1908 Robinson of Boston intubated through the mouth to the bifurcation of the trachea, sending in air under pressure through a cannula, and letting the exhaust escape by way of the remaining lumen of the trachea. Later Robinson investigated the Volhard-Sollman method of oxygen insufflation, by means of which, during animal experimentation, life could be sustained without distention of the lungs; but he was distracted from perfecting this or the air-insufflation technique by becoming interested in progressive improvements which he made in both the Brauer and Sauerbruch methods.

Mikulicz, however, must be credited with the first systematic investigation of the physiological problems besetting intrathoracic surgery. At his suggestion in 1903 Sauerbruch began a series of experimental researches, and in 1904 completed cabinets for intrathoracic surgery, using respectively positive or negative pressure.

While Sauerbruch soon discarded his hyperatmospheric apparatus in favor of his negative-pressure cabinet, Brauer, working independently, developed the first positive-pressure chamber to come into general use. The apparatus devised by Karewski resembled closely that of Bauer, as did also the initial cabinets of Janeway and Green. The devices of Tiegel and Brat-Schmieden were essentially of the emergency or laboratory type, although an effort was made to adapt them to the more exacting requirements of intrathoracic surgery on the human subject.

What Carrel has termed the "classical type" (cabinet) of apparatus has found its apotheosis in the new intrathoracic surgical pavilion of Willy Meyer at the German Hospital, New York, in which it is possible to operate differential, positive, or negative pressure at will.

Until the present popularization of intratracheal insufflation by the Meltzer-Auer technique, whatever real progress has been made in intrathoracic surgery on the human subject must be credited to the "classical style" of apparatus.

In 1908 Meltzer saw Sauerbruck doing intrathoracic surgery, and later witnessed some of Willy Meyer's operations at the Rockefeller Institute, and seeing both pleural cavities wide open and the animals continuing to breathe, but not trusting the evidence of his own eyes he went into his laboratory to verify the experiments. A year later, in association with Dr. Auer, he published an article on "Continuous Respiration without Respiratory Movements." After Meltzer had perfected the technique of intratracheal insufflation in his laboratory, Elsberg, with the assistance of Yankauer, developed an apparatus for its use on the human subject, and personally administered anesthesia by

this method for a successful thoracotomy performed by Dr. Lilienthal at Mt. Sinai Hospital in 1910.

Meanwhile, Morriston Davies, after a thorough investigation of all the intrathoracic apparatus and methods in vogue, perfected and used a hyperatmosheric device, combining both the advantages of the cabinet and intratracheal insufflation techniques, and to Elsberg, and Peck (New York) and Davies (London) belong the credit, not only of adapting intratracheal insufflation to the requirements of intrathoracic surgery, but also of demonstrating its value as a technique of narcosis in the surgery of the head and neck.

While the "classical type" of the cabinet and intratracheal style of apparatus are in apparent competition for supremacy, still each has its possibilities and its limitations, and further clinical experience alone will determine their respective utility in certain definite intrathoracic surgical procedures.

Physiological Considerations.—Progress in intrathoracic surgery has depended absolutely on the mechanical control of pneumothorax during the operative procedure. This mechanical control has varied in different methods, from that of Hook, now represented by the Meltzer-Auer technique, in which the lungs for certain periods have been so distended by a constant current of air as to preclude more or less any respiratory movements, to that of Volhard-Sollman, in which the lungs have been allowed to collapse, while a current of oxygen sustained life.

However, for all practical purposes, reciprocal breathing, under manometrically controlled positive, negative, or differental pressure, has proven the only safe method of compensating pneumothorax during intrathoracic operations upon the human subject.

Any consideration of pneumothorax involves an understanding of some elementary facts of the respiratory mechanism. Respiration is made possible in the thorax of the human subjects by a partial vacuum existing in the pleural space after the contraction of the lungs during expiration. This vacuum is represented by a varying negative pressure of from 4 to 10 mm. of mercury. Consequently thoractomy requires either positive-pressure insufflation, with or without respiratory movements, or autorespiration in the negative or differential pressure cabinet, to prevent the collapse of the lung resulting in dyspnea, displacement of the thoracic viscera, shock, and death.

With the body of the patient within the cabinet in which the air has been rarefied to approximately the negative pressure in the pleural cavity (4 to 10 mm.) and the head of the patient is outside the chamber, permitting the respiring of normal pressure atmosphere, Sauerbruch, by varying the negative pressure as required, has been able to conduct intrathoracic operations with almost the same confidence as in abdominal surgery. In the Meyer cabinet differential pressure allows the surgeon to use positive, negative, or combinations of both pressures as needed. The great distinction between the cabinet control of pneumothorax and intratracheal insufflation is that in the former autorespiration is denpended on to conserve life, and already overtaxed and weakened nerve centers are called upon to formulate respiratory impulses, while during intratracheal insufflation these centers can be made to remain passive, thereby adding a determining factor between success and failure. Moreover, in some operative procedures those muscles which participate in respiration or are rendered inactive, thereby making the use of intratracheal insufflation all the more imperative. This demand is accentuated whenever during the course of any intrathoracic procedure dislocation of the posterior lobes of the lungs inhibits the usual respiratory movements.

Respiratory movements are not only concerned in the aeration of the lungs, but also contribute a factor essential to the normal maintenance of the pulmonary circulation and of considerable importance to that of the systemic. Thus the pulmonary circulation may be regarded as of double function, the ventricular, impelling the blood onward with rapid pulsations of the cardiac rhythm, while the lungs contribute the slower but more voluminous impulses of the respiratory cycle. (Davies.)

Hence it is that during intracheal insufflation Meltzer has found it inadvisable to use a pressure which altogether suspends respiratory movements, resulting in apnea and CO_2 asphyxia, and suggests that, in so far as it is possible or necessary, the lungs be periodically deflated five or six times to secure not only a more satisfactory diffusion of the air and anesthetic in the smaller bronchi and alveoli, but also to eliminate CO_2 accumulation, and further to preserve the stimulus of respiratory movements upon the pulmonary and systemic circulations. In cases of open pneumothorax in which the respiratory mechanism is not paralyzed, spontaneous respirations offer the required aid to continuous intratracheal insufflation.

However, it is always advisable to arrange for occasional interruptions of the continuous insufflation, especially in operations in which the thorax has to be laid wide open and the posterior and inferior portions of the lungs have to be dislocated, in which condition spontaneous respirations are of no avail. The occasional deflation of the lungs insures the continuance and efficiency of the pulmonary ventilation under all circumstances. It is essential, however, that this deflation be not allowed to result in a complete collapse of the lung, for reinflation under the circumstances may leave portions of the lung atelectatio.

Moreover, such deflation is valuable as a diagnostic factor in differentiating healthy from pathological lung tissue by the change of color and the presence or absence of proper distention. Again partial deflation is useful in left-sided pneumothorax, particularly in suturing the wounds of the heart, under which circumstances hemorrhage from the heart wound, according to Friedrich, diminishes in proportion as the lungs are allowed to collapse.

The partial pneumothorax thus becomes the regulator of the hemorrhage and is allowed to persist until suture of the heart wound has been completed, after which the pericardium and pleura are closed with the lungs properly reinflated.

Extensive laboratory experiments, which have been verified by post-operative results in the human subject, prove conclusively that so far as respiratory complications are concerned intratracheal insufflation is an innocuous procedure even in the presence of the lobar pneumonia. Also it has been found in practice that the recurrent air-stream through the trachea precludes the possibility of aspirating vomited material or hemorrhage from the pharynx.

Physiologically, the intrinsic value of intratracheal insufflation is exemplified not only in the original work of Fell, but also in the laboratory

experiments of Shaklee and Githens on the treatment of strychnine poisoning, in which, although the very centers of respiration were paralyzed, intratracheal insufflation reached the climax of its usefulness as a measure of resuscitation and the conservation of life.

Meltzer has also found that anesthesia by intratracheal insufflation is far superior in many respects to the usual methods of administering ether. The anesthesia is much safer, far more readily controlled; less of the anesthetic agent is used, patients go under and come out more rapidly, and an efficient method of artificial respiration is immediately at hand to take care of untoward complications.

In recent studies on the influence of intratracheal insufflation on blood pressure and respiration, Meltzer and Githens found that a manometric pressure of from 30 to 40 mm. and a percentage of ether just sufficient to complete anesthesia, from 50 to 75 per cent. were innocuous, but that an increase of pressure and the percentage of ether for any appreciable length of time would result in an undulating fall of blood pressure, a slowly and diminished excursion of respiratory movements, with final cessation of breathing, although the heart continued to beat.

Resuscitation was possible in animals within 20 minutes by the insufflation of pure air. From the experiments it appeared that an overdose of ether first paralyzed the functions of the medulla and then much later the functions of the heart. Hence the caution in administering intratracheal insufflation to reduce the ethery percentage in ratio to the shallowness and diminished rate of respiration.

Untoward respiratory and associated cardiac complications may also result from operative manipulation of the vagi and their branches, and the resulting false apnea may be controlled by the hypodermic use of atropin.

An increase of pressure, accomplished either by means of the air current or indirectly by momentary pressure on the larynx, is valuable not only in gauging the proper distention of the lung, but also in obviating cyanosis and in overcoming the resistance of neurotic individuals to the anesthetic effects of the ether. All investigators have found it expediennt to add a tank of oxygen to their armamentarium for intratracheal insufflation. Under certain circumstances a persistent cyanosis will develop, which nothing short of oxygenation will control.

While Brauer uses the Roth-Drager, and Davies the Alcock regulating chloroform apparatus in conjunction with mechanical respiration for purposes of pulmonary anesthesia, ether seems to be a far safer agent for routine narcosis by this method.

As early as 1827 Portal produced an artificial pneumothorax without thoractomy by the injection of sulphureted hydrogen gas into the thoracic cavity to place the lung at rest when affected with tuberculosis. Holmgren pursued the same principle of treatment for unilateral pulmonary tuberculosis even in cases in which adhesions between the visceral and parietal pleuræ contraindicated its use. Hamman of Johns Hopkins is now utilizing a similar technique with nitrogen gas. In the presence of adhesions, the preliminary injection of saline solution to collapse the lung is advisable before injecting the gas to produce the therapeutic pneumothorax.

Perforation of the thoracic wall does not always result in pneumothorax, unless the opening is larger in diameter than that of the glottis, or is valve-like in character as in oblique puncture of wounds. As a rule, pneumothorax will disappear when the opening in the chest wall has been closed by the adjacent integumentary structures. These two facts have enabled surgeons, by means of tubes under water and the use of rubber tissue dressings, to allow for post-operative drainage of the thorax without artificial control of pneumothorax.

Technique of Intratracheal Insufflation Anesthesia.—Apparatus for intratracheal insufflation anesthesia has multiplied rapidly since the popularization of the method by Elsberg. However, all apparatus is similar in certain essentials. The source of air current may be provided by foot bellows, hand-driven or electrically-driven pumps, and tanks of compressed air. The air-current may pass directly into the ether container, or as is more advisable, is stored in a low-pressure tank or gasometer from which it passes into a Wolf bottle, to be heated and moistened, and thence by regulating valve, either directly into, or only partially through the ether container, thereby providing for aeration pure and simple or insufflation with varying percentages of ether.

Also a source of oxygenation is an expedient adjunct. The tube from the apparatus connects with a mercury manometer and thence to the intubation tube.

Davies, adopting Kuhn's idea of a double intubation tube, uses a manometer to gauge the inlet and outlet air pressures.

All experimenters have concluded that for the Meltzer-Auer technique a silk-woven catheter 30 cm. long and of a diameter one-half that of the glottis, usually from 22 to 26 of the French scale, serves as the best intubation tube. It should have an opening similar to the rectal tube at the tracheal end, should be absolutely smooth and semi-rigid to prevent it from being expelled by coughing or from being compressed while in position.

Its introduction is best accomplished after the preliminary introduction of narcosis by ethyl chloride-ether or nitrous oxide-oxygen-ether anesthesia.

Intubation is greatly facilitated by means of either the Jackson direct laryngoscope, Fischer's modification of Hayes's instrument, or the introducer devised by Cotton. After the patient has been deeply narcotized the mouth is opened wide and so held by a gag. The head is well brought forward and the tongue pulled forward by an assistant until the opening of the larynx is brought into view. The metal guide is introduced into the opening and the intubation tube is gently pushed onward until it is seen to pass over the epiglottis into the larynx, after which the metal guide is withdrawn and the tube is pushed further into the trachea until it meets an obstruction, which is either the wall of the right bronchus or the bifurcation of the trachea. It is then withdrawn an inch and is anchored in position to special mouth gags provided for the purpose.

The distance from the incisors to the bifurcation of the trachea is from 9 to 10 inches in the infant, 12 in a child, and about 17 inches in the adult. The glottis in the adult is one-half the distance between the incisors and the bifurcation of the trachea, and Elsberg suggests making the intubation catheter accordingly to insure greater accuracy in adjusting its location.

One-eighth to ¼ gr. of morphine hypodermically

ten minutes before the administration of ether to reduce the irritability of the larynx; or from twenty minutes to half an hour previously when preliminary anesthesia by ether is not resorted to. The induction of narcosis by intratracheal insufflation produces spasmodic coughing while the patient remains conscious.

With the intubation tube introduced to the correct position, air may be heard rushing through the catheter. Spasm of the larynx may now occur for a few moments, but is of no consequence. At this juncture the tube from the apparatus is connected to the catheter with the pressure gauge of the manometer controlling the air supply at 20 mm. and the ether percentage at 50. If the lungs are not kept properly distended by a pressure of from 10 to 20 mm. Hg, the intratracheal tube is either out of position in the right bronchus or is too small and is allowing too much air to escape by way of the trachea. In the first instance the tube must be retracted and in the second either a larger sized tube must be introduced or else slight compression of the trachea around the tube at the jugulum must be intermittently utilized. Too large a tube causes CO_2 accumulation and cyanosis.

Complete muscular relaxation is usually obtained with from 50 to 75 per cent. of ether, and during the course of narcosis the breathing is quiet, respirations are reduced by one-third, the face remains pink, while the veins of the forehead become prominent; the pulse usually remains full, bounding, and regular, the pupils do not dilate, and frequently the corneal reflex is active, so much so that the condition of the patient is rather one of analgesia than anesthesia. Reaction from the anesthesia is so rapid that care must be exercised to keep up etherization throughout the entire operation. The depth of narcosis is controlled by increasing the air pressure and the percentage of ether while at the same time avoiding a condition of apnea, which supervenens at pressures of from 30 to 40 mm. Cyanosis and the accumulation of CO_2 during the operative procedure are controlled by periodic deflation and occasional oxygenation with air. Pure oxygen is dangerous on account of its toxicity when its tension becomes too great, and it is too freely absorbed by the circulation.

At the close of anesthesia, ether is turned off, and pure air, or a combination of air and oxygen, is insufflated under slightly increased pressure to blow out the other from the trachea and alveoli. Patients come out from under the influence of pulmonary anesthesia by this method almost as soon as the insufflation is discontinued and the tracheal tube removed. Apnea is present for a few moments after the removal of the intubation tube, but regular breathing is then rapidly re-established. Post-anesthetic vomiting, headache, dyspnea, and cardiac complications are of rare occurence. Postoperative pneumonia, interstitial emphysema and pleural effusions have followed intrathoracic operations done under both cabinet and intratracheal insufflation methods and the determining etiological factor in the complication has not been readily determined. However, caution must be directed to a technical mishap which may occur, and that is an accidental injection of fluid ether into the lungs. Fischer quotes a case in his own experience in which death resulted from this contretemps and the mishap has occurred in laboratory experiments. Only apparatus should be used which mechanically precludes the possibility of such an occurrence.

Again, post-operatively, it may become necessary to resume insufflation without anesthesia to control shock, to aid flagging respiration and circulation, and to prevent serious effusions. Under such circumstances the success of Fell in saving life under the most disheartening conditions must be remembered, and the method pursued to its limits.

Aside from its value purely as a resuscitative measure in asphyxia, drowning, poisoning from drugs and anesthetics, the convulsive stage of rabies and tetanus, impaired respiratory function in certain diseases, it must also be remembered that intratracheal insufflation as a method of anesthesia is a very desirable adjunct to the surgery of the head and neck, and especially for operations on the spine when the patient must be placed flat on the stomach during the course of operative procedure.

While etherization in association with intracheal insufflation appears to be the safest form of anesthesia for intrathoracic operations, Boothby, after using the nitrous oxide-oxygen-ether technique, has been favorably impressed with the latter method, and Willy Meyer also suggests that the innocuousness of nitrous oxide may play an important rôle in conserving patients under thoractomy the additional shock of a poisonous anesthetic agent.

AN EPIDEMIC OF TYPHUS FEVER IN VAN, TURKEY.

By C. D. USSHER, M.D.,

VAN, TURKEY.

During the past two years a very fatal disease has been making terrible ravages among the soldiers of the Van, Bitlis, and Erzeroum vilayets. Many thousands have died, and the disease has not been confined to the military, though its spread among the populace has been surprisingly limited, and the mortality much less than among the soldiers.

During the winter and spring of 1912-1913 we heard reports of an epidemic in Mush which had carried off more than a thousand soldiers and four doctors. The military physicians of Van were sent there to investigate and reported that it was typhoid fever. The medical inspector of Bitlis went to Mush to investigate, returned to Bitlis, sickened and died in a hotel there. Two German teachers from Aleppo were traveling across the country for their summer vacation and stopped at the hotel. As they had no traveling bedsteads with them one of them used the bed on which the Turkish doctor had died, though of course he had no knowledge of the fact, it was ascertained by later investigations. They occupied the room from Monday till Thursday, when they left for Van. The following Wednesday one of them was taken with chill, aching, and severe fever, and died on the thirteenth day of a disease which the Turkish and quarantine doctors failed to diagnose. I spent the summer in a trip to the meeting of the Medical Missionary Association in Jerusalem. On my return I found an epidemic among the forty-five hundred soldiers in Van. There was much secrecy about it and I could get no more information at first than that it was typhoid; then I was told that it was dengue (a disease absolutely unknown in this altitude and latitude), then it was diagnosed as influenza. At this time I saw a case thickly broken out on the chest and trunk with a dark exanthem resembling very closely the appearance of measles.

The man happened to be a Protestant soldier so I called at the military physician's club and asked permission to see the patient who was in their hospital. The doctors insisted on bringing him out to me on a stretcher, the hospital being so foul that the doctors entered it with handkerchiefs to their noses, and the patients lying on the floor were packed three or four in a bed without room to step between them. While I waited groups of sick soldiers were brought from distant barracks, some of them too sick to sit alone on horseback—they were held in their saddles by comrades. As the hospitals were already taxed to their limit, these poor fellows, riding wooden pack-saddles, were sent back to their barracks. The man I was seeking to visit as a friend, not as a physician, having been brought, I was informed that he had influenza, and that the eruption was the eruption of influenza. I thought to myself that I had never heard of this eruption accompanying influenza, but not wishing to expose my ignorance. I went home and looked up the subject. On the way home I called on the general in command of the army corps and offered to put thirty beds in our hospital at the service of the sick soldiers. This and other offers of help were refused, but a few days later, money having come to pay off some whose term of service had long since expired, about a thousand men were discharged, many of them from the military hospitals, and some of them in a dying condition. Many others were sickening with the disease, and soon our hospital was filling up. It did not take long observation to determine that the disease was typhus exanthematosus.

In an epidemic some eight years ago we found calcium sulphide a valuable remedy, apparently aborting the disease very promptly. This time we had a supply of pills and tabloids on hand. They were over a year old, however, as it takes from five to twelve months to import our supplies, and we could not get the full physiological effect, even giving 24 grains in 24 hours, half a grain every half hour. To this we attributed the failure to get the same results obtained in the previous epidemic. Nevertheless our mortality in private practice and in the hospital was less than 3 per cent. while the mortality among the soldiers was about 75 per cent. I tried to induce the military and quarantine doctors to try the calcium sulphide in the military hospitals and barracks, but they refused on the ground that it was not in their books and their books said that there was no remedy which modified the disease. Then they were themselves attacked by the disease, came to our hospital, and recovered. In the hospital we lost two patients. One of them had a complication of mumps, and the other had chronic bronchitis and asthma and died badly cyanosed. Outside the hospital the only case lost was a man sixty-six years of age who had worn himself out nursing three or four other cases. In some cases with very violent delirium, neosalvarsan was administered intravenously in 0.60 gm. doses and seemed to help materially and to stop the delirium.

My object in writing this, however, is not so much to speak of the treatment as to corroborate what has already been published as to the means of transmission. As I write we have a typhus patient occupying the only available bed in the surgical ward, with a hernia case on one side of him and a popliteal abscess on the other, and we are sure neither of them will contract the disease. The epidemic has been spread by soldiers all over the country, and we hear that the American Hospital in Harpoot which has had twenty-five cases has been closed for disinfection by order of the Government. The native physicians, with few exceptions, seem afraid to go near a typhus patient, and want phenol solution and alcohol to wash their hands with if they have been in the room with one. We consider that we have proved conclusively in our hospital that the only means of transmission is vermin. Our nurses have been exposed to every other form of contagion from the breath, desquamation, discharges, constant association day and night, and all this in an over-tired condition, and not one of them has contracted the disease. The typhus patients have been put in the same ward with surgical, pneumonia, dysentery, and even confinement cases, and not a single patient has become infected in the hospital. One of the male nurses subjected himself to infected body lice, and promptly contracted the disease (incubation five days, I think). I personally removed the lice from his body. We have become so sure of the mode of infection that, being compelled by lack of bedding, we put patients with other troubles in the beds which had been occupied by typhus patients. We made no further change than clean sheets and pillow covers, and though in several cases the limit of incubation has passed three times over, there has not been a single instance of infection.

During the epidemic I had the misfortune to be laid up with a subluxation of the spine which recurred when I climbed the fifty-nine steps between our house and the hospital. This prevented my getting around as I desired for three weeks, but I was favored with the visits of a number of physicians, civil and military. Our conversations resulted in the cleaning up of the barracks and hospitals and the boiling of all of the clothing and bedding of the soldiers, which promptly put an end to the epidemic that had already carried off more than twenty-five hundred of the soldiers in Van. Nineteen officers also succumbed.

Later experiences with calcium sulphide have not confirmed our former happy results. Though there has been distinct benefit from it, we have not found it act as specifically as reported in our article on the "Therapeutics of Calcium Sulphide," published in the MEDICAL RECORD, September 25, 1909.

DIABETES MELLITUS FOLLOWING INTERVAL OPERATIONS OF BILATERAL MASTOIDECTOMY AND UNILATERAL EXENTERATION OF ETHMOID, SPHENOID AND MAXILARY SINUSES.

BY VIRGINIUS DABNEY, M.D., F.A.C.S.,

WASHINGTON, D. C.

ON December 27, 1913, Dr. Howard Fletcher, Fairfax, Virgnia, referred to me a farmer's wife, for examination of a discharging ear, which he had not seen himself. The history of this case is as follows:

Mrs. C. H. P.—No lues, no tuberculosis in family of herself or husband; no serious disease herself; never sick in bed (till two months ago, when she had influenza) save at delivery, twice; children healthy. Earache December 24 in night; drum ruptured next day; very deaf ever since. December 27: temperature normal; septic color; left nostril blocked with polyps; right middle meatus filled with thick yellow pus (chronic bilateral suppurative ethmoiditis; acute suppurative otitis media, unilateral); reports difficulty in nasal respiration for only two months; teeth carious and irregular; roots exposed; gums spongy and bleeding (Riggs' disease); discharge from left ear profuse. December 28: temperature 100° F.; snared and divulsed

eight polyps, chiefly from hiatus semilunaris, left; pus showed streptococci in abundance and a few *Staphylococci aurei*, from ear and both nostrils. December 31: snared two more polyps from middle turbinate; removed middle turbinate, which was followed by gush of pus from ethmoid labyrinth; increased flow of pus from both nostrils; temperature 98° F.; leucocytes, 8,000; mastoid very sensitive; ear discharge more watery and profuse (streptococci). January 1: morning temperature 103.2° F.; leucocytes, 15,000; mastoidectomy, left; bone thoroughly disintegrated; 25 millions stock streptococcus vaccine injected at operation; temperature dropped from 103° to 98° F. from 2 P. M. to 9 P. M., and rose again to 104° F. by midnight; no sugar in urine before operation or next day; urine scanty; no thirst other than usual after anesthetic (*i.e.* ether); right drum ruptured as patient was leaving room for operation. January 3: temperature 100.4° F.; right ear discharging freely; culture from both ears, mastoid wound and nasal chambers all showed streptococci alone; 30 millions stock vaccine at 2 P. M., temperature falling a degree and a half by 8 P. M. January 5: temperature 99° F.; discharge from right ear less. January 7: 35 millions autogenous vaccine; temperature normal. January 12: patient's condition excellent for five days; to-day temperature rose to 99.2° F.; 40 millions vaccine. January 16: temperature normal; 45 millions vaccine. January 22: right ear discharge suddenly increased; ethmoid suppuration thought original cause, along with empyema of antrum; so exenteration of ethmoid, sphenoid, and antrum done; polypoid degeneration and caries extensive in all sinuses; no sugar or albumin in urine. January 27: right mastoid painful; temperature 103° F.; mastoidectomy; extensive disease. February 3: left hospital; wounds all healing as rapidly as usual; patient benefited more than usual; gain in weight, improvement in color, and general physique very marked.

From February 5 to May 1, the mastoid wounds did not fill with the usual speed, nor did the canine fossa wound, which was the only suggestive element in the convalescence. Both middle ears began to discharge profusely May 1, and loss of weight began to be noticed by patient, who occasionally spoke of her thirst, and, once, of her eyesight being not so good as usual. May 15, she mentioned all her symptoms to Dr. Fletcher, who at once had an examination of her urine made, which showed nearly 4 per cent. of sugar. Upon the institution of proper dietetic treatment all her symptoms disappeared, one mastoid wound closed at once; the other has practically done so, and her weight has returned to within five pounds of normal. The following points are interesting: (1) no sugar despite frequent tests till three months after third operation; (2) none of the classical symptoms, such as thirst and retinitis, before this time; (3) remarkable effect of vaccine on the temperature, but none on the progress of the disease.

A MODIFICATION OF THE CRILE CANNULA.

By ALFRED KAHN, M.D.,

NEW YORK.

To my mind, the Crile cannula is the most simple cannula that we have; but its use has presented difficulties which have caused many suggestions to modify it in certain respects. To me, its most conspicuous defects are its fragility, ease in breaking; and owing to its smallness, the difficulty in handling, and thereby controlling it. Having these two defects in mind, I have endeavored to improve it and have done so in the following way: I have had an instrument made of a hard, bronze, non-tarnishing metal such as is used in the manufacture of many operating knives. This metal is hard to nick or scratch, will not rust, and will stand rough usage. The Crile cannula very often breaks at the junction of its handle portion with the cannula piece. In difficult transfusions where an artery is placed under much tension, in drawing it toward the vein for connection, I have broken many of these cannulæ. I have, therefore, modified the instrument by separating the handle and cannula parts entirely, and this presents many advantages, most important of which is a larger, longer, more solid and firm handle, which allows easy manipulation. The illustration will make the instrument understandable.

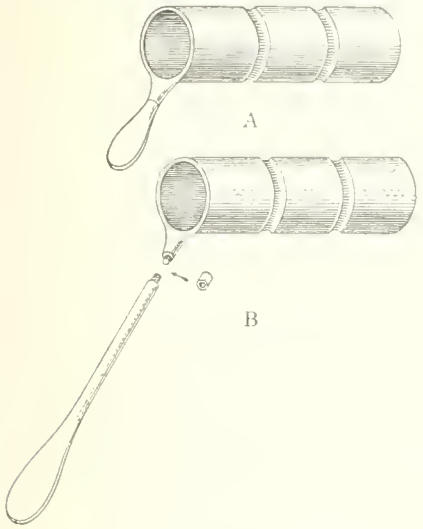

Fig. 1.—A, the Crile cannula with short handle; B, the author's modification, with handle unscrewed showing the lock-nut.

After the artery and vein are connected, the rod is unscrewed from the cannula. There is no handle dangling between the vessels; only the little cannula tube. This makes the operation much more clever. There is a small lock-screw between the rod and cannula pieces.

34 East Fortieth Street.

Medicolegal Notes.

Malpractice—Evidence.—In an action for malpractice it appeared that the plaintiff consulted the defendant for catarrh, from which he had for years been a sufferer. He testified that he had a cold, and so informed the defendant. The defendant performed two operations on the nose, removing the anterior ends of the lower turbinals. After the second operation, a mastoid abscess appeared, and there was another operation for this. The mastoid operation left a depression in the head back of the left ear, which some months afterwards was filled with paraffin injected under the skin. The paraffin was injected three times, but each time sloughed out. After a verdict for the plaintiff a new trial was granted. On appeal it was held that there was evidence sufficient to take the case to the jury, but not to warrant the direction of a verdict for the defendant. It was held competent for the plaintiff, though not an expert witness, to testify that he had a severe cold at the time, and that he so informed the defendant.—Swadner v. Schefcik, Minnesota Supreme Court, 144 N. W. 958.

Claim Agent's Authority to Employ Doctor.—In an action by a physician to recover for medical attendance upon an injured employee of the defendant street railway, on the ground that it had been authorized by the defendant's claim agent, evidence that the plaintiff had been paid by the defendant for the treatment of other injured employees brought to him by a former claim agent was held to be admissible, as showing the extent to which the defendant held out the authority of its claim agents, and as showing how far the plaintiff was justified in assuming that they had such authority.—Pritchard vs. Old Colony St. Ry. Co., Massachusetts Supreme Court, 103 N. E., 692.

Liability of Husband for Unrequested Operation on Wife.—It is held that a husband is not liable to a surgeon who operated upon his wife during the husband's temporary absence from the city, where the wife did not request the operation, but merely passively acquiesced in it, and no person having any power of agency for the husband requested or authorized it.—Kennedy vs. Benson, New York Appellate Division, 144 N. Y. Supp., 787.

MEDICAL RECORD.

THE DUMDUM MYTH.

THE German Emperor recently sent a note to President Wilson complaining that the French and English were using dumdum bullets, a practice condemned by all civilized nations as inhuman. President Poincairé and Sir Edward Grey have officially and categorically denied the charge, and there can be no doubt whatever that the Emperor was mistaken. The Allies have made the same accusation against the Germans, and, of course, are equally mistaken. The explanation of the error on both sides is not far to seek. In an editorial comment on Colonel La Garde's recent work on "Gunshot Injuries" in the MEDICAL RECORD of May 2, we prophesied that there would be a return to inhumanity in the next war because of the use of the spitz bullet recently introduced by Germany and adopted by several other armies, that of Great Britain and the United States among them. This bullet is quite short, of conical shape, and tapers so gradually that the center of gravity is thrown back near the base; consequently, in spite of its great initial velocity and flat projectory, it has a tendency to turn sideways upon meeting any obstacle, although it will go through the soft parts making a small clean-cut channel, and do little or no injury unless it hits a vital organ. In the article on "Gunshot Wounds" in the fourth volume of the "Reference Handbook of the Medical Sciences" Colonel La Garde says of this bullet: "The least resistance upsets it and in turning at great velocity the wounds it inflicts are very much lacerated and otherwise attended with destructive effects which are not unlike the wounds inflicted by dumdum bullets. For this reason, the new pointed bullet is a great disappointment to military surgeons. In experiments which we conducted two years ago, we found the resistance encountered in the hip-joint, chest, and abdomen of cadavers sufficient to cause the bullet to turn and the resulting wounds were like those of an expanding or metal-patch bullet. Colonel Roosevelt, in his 'African Game Trails,' refers to the wounds of the pointed bullet as having a slashing effect against large game. At 280 and again at 180 yards he brought down two bulls each with one shot, the bullet making 'a terrific rending compared with the heavier ordinary shaped bullet of the same composition.'"

In all probability these spitz-bullet wounds have been mistaken for the explosive lesions of the dumdum bullets, and the accusation of the German Emperor was therefore made in good faith, but in curious ignorance of the effects of the missiles used by his own army. Nevertheless the dumdum or a similar bullet has been occasionally used in this war, but by civilians. East Prussia, for instance, is a game country and the hunters there use the dumdum type of bullet in the chase. The Russian invaders of that country have been frequently attacked by "snipers" who used their hunting rifles loaded with dumdums. It is possible that the civilian hunters in eastern France did the same, and so an occasional dumdum may have been found in the bodies of the German wounded, but that the armies of any of the nations now at war are using this bullet is altogether improbable. They have no occasion to use it, for the spitz bullet is almost as destructive and its employment is just as brutal.

THE PERIODIC ASTHENIAS.

A DISTINCT clinical entity characterized by the occurrence, at definite intervals, of crises of fatigue, is described by J. Dejerine and E. Gauckler in the *Presse Médicale*, June 17, 1914. They point out that in the domain of psychiatry almost all the constitutional psychoses are dominated by the notion of periodicity. For instance, paranoia, the periodic psychosis, manic-depressive psychosis, circular insanity, and more particularly psychasthenia and cyclothymia are all characterized by their periodicity. In many cases of cyclothymia, associated with the attacks of psychical depression there is also a pronounced physical fatigue. There are some cases, however, in which there occur periodically attacks of physical depression which are not accompanied by any mental disturbance. These cases are regarded by the authors as of common occurrence clinically and are designated by them under the name "periodic asthenias." Similar crises in a minor form occur as a normal phenomenon in almost every individual. Extremely rare are those beings who possess a perpetual physical equilibrium, just as rare as those who display an even tenor of mind and character. Devoid of any psychological element, the mild asthenic crisis constitutes a simple and slight crisis of physical weakness. The individual affected gives evidence of a normal intellectual and moral activity. He manifests, however, repugnance for every physical effort; in fact, the slightest exertion causes extreme fatigue. There is at the same time a more or less pronounced loss of sexual desire. Some of the patients attribute their condition to atmospheric and possibly to transitory arthritic changes. The periodic asthenias occur equally in men and in women, usually in early life, and sometimes after infectious diseases such as typhoid fever or severe influenza. The attacks rarely exceed one week in duration and may last only one or two days. In some cases they recur three or four times a year, and in other instances they may be repeated every fifteen days.

Apart from their periodicity the chief character-

istics of these attacks are their sudden appearance and disappearance and the absence of any apparent cause. There is a type of these cases in which the crises of fatigue are particularly severe. Physical effort is almost impossible. There may or may not be certain associated modifications in the pulse and arterial tension, changes in the sebaceous glands and hair follicles, digestive disturbances, etc. Attacks of migraine are frequently observed. Sleep is normal and the appetite is usually good. Frequently a loss of weight accompanies the crises. This loss may be considerable, amounting in rare instances to from ten to forty pounds. On the other hand, in some cases there may be a gain in weight. The duration of the major attacks is on an average two months, but there are cases which last much longer, in this respect resembling an attack of melancholia. The termination of the crisis is remarkably sudden. No etiological clue is furnished from the viewpoints of sex, temperament, constitution, heredity, and pathological antecedents.

In the diagnosis of this condition, the clue to which resides chiefly in the periodicity of the attacks, a number of other conditions must be ruled out, such as ordinary physiological fatigue; the subjective fatigue occasionally observed in neuropaths; the asthenia associated with organic disease, such as tuberculosis, and disturbances of the ductless glands; constitutional neurasthenia, particularly in young people; syphilis, either inherited or acquired; and finally, paresis, which may be manifested in the beginning by attacks of marked asthenia. Frequently the diagnosis is made difficult by the presence of a secondary neurasthenia.

In seeking the cause of the periodic asthenias, the attention is firmly riveted on the ductless glands. The asthenia of suprarenal origin is well known. Similarly, asthenia is a marked symptom of myxedema and of exophthalmic goiter. Experimental and therapeutic tests have shown that the pituitary gland stimulates both striated and smooth muscle fibers. It would appear as if the physiological efficiency of the muscular system is dependent upon an equilibrium of the endocrinous organs. The interconnection of all the glands of internal secretion is a fact that has been demonstrated in many ways. The functional or organic impairment of any one of them leads to an impairment of the entire group. One fact stands out in the study of the functions of the ductless glands, namely, the periodicity of these functions and of their disturbances. This is particularly the case with the ovary and the thyroid. The periodicity of the phenomena of exophthalmic goiter is fully recognized. On the basis of the above facts, Dejerine and Gauckler believe that the periodic asthenias represent a rupture of the endocrinous equilibrium, which disturbance impairs the sthenic function of the ductless system. The rupture may be spontaneous or it may be synchronous with biliary or arthritic manifestations.

The therapeutic test, however, throws the strongest light on the etiology of this condition. It has been found that the attack subsides upon the administration of thyroid extract in conjunction with the total extract of the pituitary gland. The dosage is from 0.10 to 0.15 gram of the former and 0.25 to 0.50 gram of the latter. With this medication the attack is brought under control in three or four days. The doses are then diminished to 0.05 to 0.02 gram and to 0.10 gram, respectively. Other elements in the treatment are the enforcement of complete rest during the attacks, and careful supervision of the general hygiene during the intercalated periods.

One of the important points brought home in the consideration of this condition is the conception of physical crises of fatigue entirely distinct from but comparable with the crises of mental depression, and having possibly a similar pathogenesis. Related to neurasthenia solely by virtue of their similar symptomatology, the periodic asthenias may be conceived as a melancholia of the body just as there is a melancholia of the mind.

THE PUMPKIN AS A DIURETIC.

THAT common articles of food may possess in addition to a high dietetic value certain medicinal virtues is indicated in the use of oatmeal as a diabetic cure, in the employment of buttermilk in gastrointestinal disorders, in the administration of acid fruits as antiscorbutic remedies, etc. A. Kakowski in the *Zeitschrift für physikalische und diätetische Therapie*, June and July, 1914, extols the value of the pumpkin when administered in large quantities in the treatment of nephritic edema. He finds that it fulfills the following requirements of the ideal diuretic food: it should contain considerable water and natural salts, but should be relatively free from sodium chloride; it should be well borne by the alimentary tract and should act as a mild laxative; it should have nutritive value and should be palatable; it should not irritate the kidneys and should not give rise to harmful metabolic products; and it should be easily obtainable, cheap, and easily preserved.

The edible portion of the pumpkin is prepared by Kakowski in the form of a porridge, by being cut into small pieces, covered with water, and boiled over a slow fire for two hours. It is administered to the patient with butter, milk, or cream, or preferably mixed with a rice soup. The preparation most agreeable to the patient is one in which the pumpkin is boiled with milk or with cream.

The pumpkin cure was employed in severe cases of chronic nephritis in which an edema had been rebellious to the entire range of medicinal diuretics. Long standing and massive edemas disappeared within a short time under this method of treatment. Diuresis occurred after the use only of enormous quantities of pumpkin, varying from three to six pounds per day, and in most cases directly proportional to the amount of this food that was eaten. The diuresis occurred only during the period of administration. The number of casts rapidly diminished, and the reaction of the urine became alkaline. There was no evidence of any irritating effect upon the kidneys nor of any otherwise harmful influence upon the body. In one of the author's cases as much as 252 pounds of pumpkin were administered

in the course of 80 days without giving rise to any untoward effects apart from large fluid stools. In addition to its diuretic action the pumpkin is said by Kakowski to have a high nutritive value, which fact is of particular importance in the case of chronic nephritics in whom the diet is usually greatly restricted.

A Final (?) Word on the Benzoate of Sodium Controversy.

Three years ago, when Dr. Wiley's partisans were still inveighing against the findings of the Referee Board regarding the alleged poisonous action of sodium benzoate when used as a preservative of jams and meats, they claimed to derive much comfort from the results of a German investigation of the subject. The German Government, having become interested in the American dispute, had requested a board of experts to give an opinion on the use of benzoic acid and its salts in the preservation of food. This commission criticised the findings of the Referee Board on the ground that its experiments with large doses of benzoates were of too short duration, and conjectured that ill results might follow the long-continued administration of the preservative in very large doses. It also advised against the use of benzoates in food on the theoretical ground that, though they were evidently innocuous in small doses, one might eat and drink in the course of the day so many things containing them that a sufficient quantity might be taken to be injurious. The commission stated, however, that one-half gram (7½ grains) of benzoic acid or its salts consumed in divided doses throughout the day, must be regarded as harmless to the human body. This was sufficiently corroborative of the findings of the American Referee Board to convince any unprejudiced observer that the United States Government was justified, on the strength of this Board's report, in permitting the use of benzoates as a preservative, provided the fact of such use was stated on the package. Some more recent experiments made by Drs. Rost, Franz, and Weitzel of the German Imperial Board of Health (Arbeiten aus dem Kaiserlichen Gesundheitsamte, xlv, 425) have confirmed the previous findings as to the innocuousness of small doses continued throughout a long period and have shown that the fears expressed by the previous experimenters were groundless. They found that dogs could take daily doses of one gram per kilogram of weight of the animal for weeks and months without showing any toxic effects. This is the equivalent of over an ounce and a half per day for a man of 110 pounds, or 50 kilos, weight —a dose which could not possibly be taken in any amount of jam or other preserves that could be eaten in twenty-four hours. Rabbits could take even larger doses, from 1.5 to 2.4 grams per kilo of animal weight, the equivalent of about two to four ounces for a small man. This ought to dispose of the question finally, but probably will not, for those who were misled by the spectacular but not altogether scientific experiments of Dr. Wiley with his "poison squad" will never acknowledge themselves convicted of error by the German Imperial Board of Health after they have rejected the testimony of such men as Remsen, Chittenden, Herter, and Long, who composed the American Referee Board.

Solubility of Gallstones.

The discovery that human gallstones vanish when placed in the aseptic gall-bladder of the dog has encouraged physicians to search for solvents for these bodies *in vivo*. Thus far we know little of their relative solubility, which must depend largely upon their chemical composition. Although they consist so overwhelmingly of cholesterin, there is more or less calcium to be reckoned with. We know nothing of the differences between bile which forms stones and bile which does not. This subject was discussed by the Niederrheinische Gesellschaft fur Natur und Heilkunde of Bonn at their last meeting (*Deutsche medizinische Wochenschrift*, July 30). After Leo had related the results of his research on the dog and had expressed his belief that Carlsbad salts could dissolve gallstones, Prym announced that cholesterin is simply absorbed by the wall of the gall-bladder. Grube added that the disappearance of these transplanted stones could not be attributed to the Carlsbad water given the animals. Leo in closing the discussion showed that his researches were rigidly carried out, with controls. While not denying the spontaneous absorption of almost pure cholesterin calculi he insisted that the Carlsbad water hastened the process.

News of the Week.

The Red Cross.—The American Red Cross ship sailed from New York on Sunday of this week, having been detained several days by the necessity of having only American citizens in the crew. The Red Cross unit for Servia, consisting of Drs. Edward W. Ryan, J. C. Fonovan, and W. T. Ahearn, with Miss Mary E. Gladwin as supervising nurse, sailed earlier in the week on the Greek ship *Ioannina*.

The Illinois Health Department is to be remodeled if the report of the State Efficiency and Economy Commission appointed to consider a plan of reunion is adopted by the Legislature. It is proposed that the State health department should consist of a State board of health of five appointed unpaid members and a salaried health commissioner. The health commissioner is to be the executive head of the department and the board of health will act in an advisory capacity. In the department are to be included bureaus of vital statistics, of foods, of drugs, and of sanitary inspection. The scheme also contemplates boards to examine and license physicians, pharmacists, dentists and nurses, with power to revoke such licenses for just cause.

The Straus Milk Stations.—A report compiled by Miss Annie Nason, superintendent of the Nathan Straus Laboratories, which was recently issued, shows that the output of milk from eighteen stations amounted to 2,148,119 bottles in the past year. Besides this, during the three summer months, 1,747,984 glasses of pasteurized milk were sold at the stations in the parks and on the recreation piers. This completes the twenty-third year of the work of distributing pasteurized milk for babies.

A Safety Congress of Mayors has been called to meet in New York City on December 14 and 15, in connection with the second international exposition on safety and sanitation. The American Museum of Safety has sent out special invitatione to the mayors of all cities with a population of over

25,000, urging them to attend Congress together with the officials of their various municipal departments which have to do with public health, safety and welfare.

The Death Rate in New York.—The mortality during the week ending September 5 was considerably above that of the week previous, the death rate jumping over one-half a point per 1000 of the population. Compared with the corresponding week of last year the most notable feature of the week's mortality was the large increase in deaths from tuberculosis, violence, and from causes other than those generally styled prominent. The increased mortality from pulmonary tuberculosis was distributed among all the boroughs, each borough showing a considerable increase over that of last year. The cause of this increase was probably due to the high temperature on several days during the week hastening the deaths of many of the sufferers from this dreaded disease. There were twenty-five more deaths from violence, each borough showing an increase, the greatest increase being in the Borough of Brooklyn. Typhoid fever showed an increase of thirteen deaths over the figures for the corresponding week of 1913. The mortality for the first thirty-six weeks of this year was 14.05 per 1,000 of the population as against a rate of 14.33 for the corresponding period in 1913, a decrease of 0.28 of a point. The continuance of this rate would mean a saving of 1,563 lives in the year.

Septic Sore Throat a Notifiable Disease.—The New York City Department of Health has included septic sore throat among the infectious diseases all cases of which must be reported by the attending physician.

The Rhode Island State Medical Society held its regular quarterly meeting on September 3 at the State Sanatorium at Wallum Lake. The members entertained themselves in the forenoon with baseball and tennis matches and fishing on the lake. Dinner was then served in the main dining-room of the Sanatorium and after that the meeting was held with Dr. Chesboro, Vice-President, in the chair. Dr. H. L. Barnes, superintendent of the Sanatorium, read a paper entitled "Hints on the Recognition and Care of Consumptives for Busy Practitioners."

Economy in Tooth Filling.—In a recent number of the *Zahntechnische Wochenschrift* dentists are urged not to use any gold in teeth filling as long as the war continues. The paper estimates that the gold ordinarily consumed in dental work in Germany amounts to at least one million marks ($250,000) within seven months.

Personals.—Major Joseph Ford, Medical Corps U. S. Army, has been appointed military observer with the Austrian Army.

Dr. D. A. K. Steele has been appointed Senior Dean and Head of the Department of Surgery in the College of Medicine of the University of Illinois. It was largely through Dr. Steele's efforts that the College of Physicians and Surgeons became an integral part of the University of Illinois as its permanent Medical Department.

Dr. Otto Kiliani of this city, is serving as chief surgeon of a military hospital in Munich.

Dr. C. B. Murray has removed to 1143 Lexington avenue, New York.

Resigning British Honors.—Following the example of the emperor who is reported to have resigned his commission in the British and Russian military and naval services and sold the various stars and crosses given him by the rulers of these countries, the professors in the German universities have declared their intention to renounce all honorary membership and other distinctions bestowed upon them by British universities and scientific societies. Professor Roentgen also has given to the German Red Cross the medal presented to him by the Royal Society of Great Britain in recognition of his discovery of the *x*-ray. The medal, which is of gold to the value of $250, will be melted down. All of which, to the neutral mind, seems puerile and peevish rather than really patriotic.

The Travel Study Club of American Physicians, which made a successful study tour of Europe last year, has completed the plans for its 1915 study tour to the A. M. A. meeting in San Francisco, Honolulu, Japan, the Philippines, and China, with optional return via Siberia and Europe (war permitting) or via Canada. All those interested are invited to communicate with the Secretary, Dr. Richard Kovacs, 236 East Sixty-ninth street, New York.

American Hospital Association.—The sixteenth annual session of this association was held in St. Paul, Minn., during the last week in August. The meeting was very largely attended, over one thousand hospitals of the country being represented. The officers elected to serve for the coming year were: *President*, Dr. William O. Mann of the Massachusetts Homeopathic Hospital, Boston; *Vice-Presidents*, Dr. A. B. Ancker of the St. Paul City Hospital, Dr. W. W. Kenny of the Victoria General Hospital, Halifax, N. S., and Miss Ida M. Barrett of the Grand Rapids, Mich., Hospital; *Secretary*, Dr. H. A. Boyce of the Kingston, Ontario, General Hospital; *Treasurer*, Dr. Asa Bacon of the Presbyterian Hospital, Chicago. The report of the Committee on Legislation commended the trained nurses in Oklahoma for their efforts in securing registration laws; declared that Iowa has the best State laws governing hospitals and nurses; that Chicago leads municipalities in this direction, and scored the California eight-hour-day law, which, in the opinion of the committee, is playing havoc with hospital routine and efficiency in that State. Announcement was made that the national hospital bureau will open in New York on May 4, 1915. The institution among other activities will make emergency purchases of supplies in this city for small hospitals which do not have ready access to large markets.

The National Medical Association, a society of physicians, dentists, and pharmacists of the colored race, met in sixteenth annual session at Raleigh, N. C., during the last week in August. The following officers were elected: *President*, Dr. F. S. Hargraves, Wilson, N. C.; *Vice-Presidents*, R. C. Brown, D.D.S., Richmond, Va.; W. A. Jones, Ph.G., Winston-Salem, N. C. *General Secretary*, Dr. W. G. Alexander, Orange, N. J.; *Assistant Secretary*, Dr. G. R. Ferguson, Charleston, S. C.; *Treasurer*, Dr. J. R. Levy, Florence, S. C.; *Pharmaceutical Secretary*, H. B. Marable, Ph.G.; *Dental Secretary*, S. L. Edwards, D.D.S. The association will meet next year in Chicago.

Medical Society of the Missouri Valley.—The twenty-seventh annual meeting of this society will be held in Colfax, Ia., Thursday and Friday, September 17 and 18, 1914, under the presidency of Dr. Flavel B. Tiffany of Kansas City. The scientific program will comprise twenty-five papers and two orations by prominent men in the profession.

On Saturday, September 19, the society will be entertained in Des Moines; clinics, both medical and surgical, will be held during the day to which all those in attendance at the meeting are invited. The secretary of the society is Dr. Charles Wood Fassett of St. Joseph, Mo.

Obituary Notes.—Dr. WILLIAM L. DUDLEY, formerly dean of the medical department of Vanderbilt University, died suddenly on September 8. He was born in Covington, Ky., April 16, 1859, and was graduated from the University of Cincinnati in 1880. He was a chemist by profession, his degree of M.D. being an honorary one bestowed by the Miami Medical College in 1885. He was demonstrator of chemistry in 1879 and 1880, and professor of chemistry and toxicology from 1880 to 1886 at the Miami Medical College. In 1886 he was appointed professor of chemistry at Vanderbilt University and was dean of the medical department from 1895 to 1913.

Dr. JOHN C. HALLAM of St. Louis, Mo., a graduate of the Marion-Sims College of Medicine, St. Louis, in 1899, and a member of the American Medical Association, the Missouri State Medical Association, and the St. Louis City Medical Society, died at the home of his mother in Centralia, Ill., on August 15, aged 37 years.

Dr. DUDLEY LEAVITT of West Stockbridge, Mass., a graduate of the College of Physicians and Surgeons, New York, in 1890, died at the House of Mercy Hospital, Pittsfield, after a long illness, on August 23, aged 50 years.

Dr. JOSEPH A. UTTER of Crawfordsville, Ind., a graduate of the Pulte Medical College, Cincinnati, O., in 1880, died at his home suddenly on August 21, aged 67 years.

Dr. THOMAS B. OWINGS of Ellicott City, Md., a graduate of the University of Maryland, School of Medicine, Baltimore, in 1852, and the oldest practising physician of Howard County, died at his home, after a short illness, on August 28, aged 84 years.

Dr. JAMES B. GARVEY of Dunmore, Pa., a graduate of the College of Physicians and Surgeons, Baltimore, in 1884, and a member of the American Medical Association, the Medical Society of the State of Pennsylvania, and the Lackawanna County Medical Society, died suddenly, from acute indigestion, at his home on August 23, aged 71 years.

Obituary.

H. SEYMOUR HOUGHTON, M.D.

NEW YORK.

Dr. H. SEYMOUR HOUGHTON, an ex-president of the Medical Society of the County of New York, died suddenly of heart failure on Friday of last week. He was born in this city in 1862 and was graduated in arts from Amherst College in 1883. He studied medicine at the Bellevue Hospital Medical College and received the degree of M.D. in 1886. After a term of service as intern at Bellevue Hospital he spent a year in foreign study and then began practice in this city. He was a member of the Medical Societies of the County and State of New York, of the Academy of Medicine, of the American Medical Association, of the Society of the Alumni of Bellevue Hospital, of the Hospital Graduates' Club, and of the West End Medical Society. In addition to serving a term as president he was one of the board of censors of the County Society from 1906 to 1913.

Correspondence.

LONDON IN WAR TIME.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—It is now a month since war began, and there is little surface indication of what is going on. The streets for weeks have been filled with marching troops, but not until yesterday were any wounded men brought from the Continent. No one knows more than the bare fact that there is a loss of six thousand men which appeared in the newspapers yesterday, but I learn from a good source that there was up to the end of the great battle which ended on August 28, nearly four times that number among the English soldiers. No one knows the great loss sustained by the Germans, and we have no figures disclosing the Belgian and French casualties, but they so far probably nearly appraise one-half of those reported for the entire Civil War in the United States.

It is needless to say that most efficient medical and surgical provision has been made in this systematic and thorough-going little island. I saw Sir Arthur Slogget, the General Director of the Medical Corps, a few days ago, who told me there was provision for half a million wounded. Of course the old hospitals, such as Netley, on Southampton Water, with a prebellum capacity of 1,080 beds, the Cambridge Hospital at Woolwich with 650, the hospitals at Greenwich, Hounslow, York, Fleetwood, Milton at Gravesend, and Milbank, are likely to be filled, but there are naval hospitals at Harwich, Portsmouth, and elsewhere that have already received many wounded sailors. All the London general hospitals are prepared for patients, and the care of Territorial troops will be their chief work. The London Hospital has been the first to receive its quota, and Sir James Fowler, with his associates are up to their ears at work. A special board, which includes Sir Bland-Sutton, Sir Arbuthnot Lane and Dr. H. D. Rolleston, with others, are controlling matters locally, and excellent results are expected. Not much is said about the so-called base hospitals, but it is to be hoped that some means will be adopted to avoid tedious transportation from the various ports of debarkation, thus saving the badly wounded and those suffering from shock additional exposure. It would be well if pavilion hospitals, like that of the Lincoln Hospital at Washington, D. C., during the War of the Rebellion, to house one thousand or more soldiers, could be erected at various points at the seashore. Of course at such a time everyone vies with everyone else to offer his home for hospital purposes and some of the greatest homes in England have been accepted, but, unfortunately, many of them have been found to be defective, so far as sewage and drainage are concerned. The big house of the Duke of Devonshire, in Piccadilly, is already occupied by the Red Cross Society, and a party of American Duchesses, headed by the Duchess of Westminster, have established a large hospital in a private house in the interior. Sir Alfred Fripp is the consulting surgeon, and much money has been raised for maintenance. Some people think it a mistake.

The reception of soldiers by families seems to be popular, but practical men shake their heads at the prospect of prolonged convalescence, especially if there is a pretty nurse or a sympathetic and eligible daughter of the house. Some of these homes are far away from railroads or medical aid,

and it is felt that the patient will not be as well as in a regular hospital.

A very extensive system of military sub-hospitals has been established in England so that now there are 150 organized in groups with a central hospital for each. In addition there are sixty civic hospitals. Other buildings are being converted, among them the Yarrow Convalescent Home at Broadstairs and the Royal Orphan Asylum. The Royal Victoria Hospital at Netley receives the most serious cases, all sick and wounded being landed near there at Southampton Docks.

The cases are, of course, of all kinds, but a very large number are wounds of the feet and legs and this is explained by the fact that the Germans do not as a rule take aim, but fire point blank while the piece is held at the hip. Most of the gunshot wounds are of the circular, clean-cut kind made by Mauser bullets, but there are a goodly number made by shrapnel or shell fire. This was found to be the case after the naval engagement of last week. Men from this were landed at Harwich with such grave injuries as the loss of arms or legs or other major injuries. The transport has also brought home many men suffering from acute rheumatism incident to exposure.

The neurological field is covered, and it is probable that Dr. Farquhar Buzzard and some of his colleagues of the Queen Square Hospital will be ready to give advice as to the necessity for laminectomy and craniectomy. Wise counsel of this kind will doubtless save many a life, or avert subsequent crippling and uselessness.

The Director General of the Medical Corps is an ideal officer. He is an alert, thin, wiry man, with a close cropped mustache and nervous manner. A keen executive, with plenty of knowledge and experience, he is exactly the man for the place at this time. Those who know him love him, especially the young men of the service, for he is tactful and kind and has little or no "side." It is unnecessary to speak of the medical corps, who are a scholarly and efficient lot of doctors—we shall hear from them later.

Many women are taking lessons in nursing, and the other day nearly 2000 presented themselves at the Polytechnic room to receive instruction and to offer their services for the field or elsewhere. It was necessary to divide this large number into classes of 500. Already volunteer nurses and physicians are going to the Continent. One hundred and thirty-five fully trained surgeons and nurses have been sent by the order of St. John of Jerusalem. Fifty hospital orderlies have gone to Havre; sixty-eight have been supplied to London hospitals.

ALLAN MCLANE HAMILTON.

LONDON, September 5, 1914.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

WAR NOTES—ANTITYPHOID INOCULATION—APPEAL OF CHIEF ARMY MEDICAL AUTHORITIES—OTHER DISEASES EPIDEMIC IN ARMIES—HOSPITAL PROVISION FOR WOUNDED IN LONDON AND COUNTRY.

LONDON, September 4, 1914.

THE war overshadows all our life and conversation. No one will talk of anything else except for a few sentences and then some subject connected with it is sure to come up. With brother professionals the danger of epidemics is ever present for they know that in most campaigns disease is more fatal than the sword. In the South African war the deaths from typhoid alone exceeded the number of men who fell in action. And yet the medical staff of the army is so satisfied of the efficiency of antityphoid inoculation as to wish it were made compulsory, as I understand it is with you and that your army is free from the disease. The Royal Army Medical College is thoroughly convinced of the protective value of inoculation and maintains a large stock of the vaccine from which it has supplied immense numbers of doses since the mobilization. It still continues the preparation of the vaccine under Major D. Harvey who has the kindly help of Sir A. Wright and the Lister Institute as far as he may desire it. There will therefore be at the disposal of the army medical staff ample supplies and the demand for compulsion is growing. Moreover it is being urged that the territorial forces should be inoculated and Col. Sir W. B. Leishman has appealed to the surgeons of this force to join in the efforts made to secure protection. He tells them that the pronounced benefits and harmlessness of the procedure are admitted by everyone who has any experience of it. It would certainly, he holds, be most rash to assume that the forces serving at home will not be exposed to the danger of epidemic typhoid and the value of inoculation is so well recognized in the regular forces that in foreign stations the surgeons have no difficulty in finding volunteers for the protective; thus he states that about 93 per cent. of the British garrison of India have undergone inoculation, and typhoid, which formerly caused from 300 to 600 deaths per annum, was last year responsible for less than 20.

The appeal of Sir W. B. Leishman has been endorsed by Professors Dreyer and Walker of the Pathological Department of the University of Oxford, who assert that the facts as to inoculation are indisputable and within the comprehension of every intelligent person. It is therefore high time that the Army Medical Department be empowered to insist on compulsory inoculation—that they should have to persuade officers and men in a time of war they pronounce well-nigh incomprehensible. Then they go on to direct attention to the fact that there is evidence that in some other diseases it seems probable that a degree of protection may be obtained from suitable vaccines.

They mention as examples cholera and dysentery, though as to the latter they recognize that the question is open to some uncertainty. They seem to be regarding the diseases from their epidemic tendency. From another point of view it might be suggested that sepsis would be a much more likely condition to be influenced by this method of treatment.

Many of the hospitals in London and large cities have placed at the disposal of the government a large number of beds for the reception and treatment of the wounded and sick invalided from the front.

The London Hospital was asked on Sunday if they could arrange to convey the first arrivals from the railway station to their institution. The secretary telephoned to the member of the committee he thought most likely, who replied—yes, and in half an hour he was able to send a van to the hospital for a supply of mattresses, pillows, etc., for the comfort of the wounded to be met at the station with a dozen other vans as well as this. This was

certainly a feat for the hospital and the member of the committee, Mr. Alfred Salmon.

On Wednesday another ambulance train brought up 127 wounded to the same station (Waterloo) but more time had been allowed and plenty of vehicles were in readiness to transfer them to their several destinations. The same day Bristol welcomed 130 wounded from Southampton which they reached by water and were sent on by ambulance train and conveyed to the Royal Infirmary. At Leicester 127 who had been wounded at Mons arrived in an ambulance train and were taken to the North Midland Hospital. These are only given you as samples of the provision being made by hospitals throughout the kingdom and in all cases the men are received with the heartiest welcome by crowds of citizens.

The report of the Select Committee on Patent and Proprietary Medicines which I briefly noticed the day after its publication last week is rather an important document extending to twenty-eight pages. It recommends that the administration of the law governing the advertisement and sale of these secret medicines and appliances be coordinated and combined under the authority of one Department of State. Further that this should be part of the work of a ministry of public health as soon as such a department is created. Until then it might be undertaken by the Local Government Board. A register of manufacturers, proprietors, and importers of these secret remedies it recommends should be kept by the department concerned and every one applying for registration should be required to make an exact and complete statement of all the ingredients and the proportions of them (other than wine and alcoholic strength of medicated wine), together with a statement of the therapeutic claims made or to be made for the article and a specimen of it to be furnished. This information will not be disclosed unless in exceptional cases, but the statements are to be controlled by analyses made confidentially by a government chemist. It is advised that a special court or commission be constituted with power to permit or prohibit the sale in the public interest and it is suggested that this might be such a judicial authority as a metropolitan magistrate sitting with two assessors, and that the president of the Local Government Board, or the Minister of Health, if such should come into existence, might have power to institute proceedings to enforce the law. In case of prohibition an appeal to the high court would be allowed. The authority would have power to require the name of a poisonous or potent ingredient to be shown upon the label. There are other recommendations as to the inspectors for the authority, the examination of advertisements, and the prohibition of some and of false trade descriptions, amendments of the stamp act, fees for registration, and so on.

A good deal has been said about the scarcity of some drugs and some have declared it amounted to a famine of the numerous chemicals usually obtained from Germany. A considerable rise in prices has been made on the strength of the shortage but it is hardly likely to last long for there are large stocks in the country and surely before these are consumed our own chemists or yours should be able to supply the demand. German chemists no doubt have excelled in the production of some drugs but as to a great number of compounds they have foisted upon us these have been accepted as useful by many who would have been better without them.

FIFTH ANNUAL SESSION OF CLINICAL CONGRESS OF SURGEONS OF NORTH AMERICA.

(From Our Regular Correspondent.)

In addition to the meetings held in the Grand Hall of the Hotel Cecil, on the evenings of July 28-31, sessions were held in the ballroom of the Hotel Savoy which were devoted to the discussion of certain surgical specialties. These meetings were exceedingly well attended, and the papers read and discussions thereon dealt with subjects of great interest presented by men of world-wide reputation.

On the evening of Tuesday, July 28, Dr. Charles W. Richardson of Washington, D. C., read a paper on congenital obstruction of the post-nasal orifice in which he said that the occurrence of this condition was described by many writers as a very infrequent form of nasal deformity, but that when the number of cases reported were considered one could but be impressed with the relative frequency of this type of nasal obstruction. He pointed out that it was possible that many cases of this kind of deformity had been in the past and even at the present time were unrecognized at birth as such, and when speedily dying, as a result of the obstruction to respiration, were placed under the general class of asphyxia neonatorum. The number of observed cases in children and adults had increased greatly during the past 20 years, but the number of cases observed in the newly born had not increased in the same proportion as the cases observed later in life. He believed this to be due to the fact that the general practitioner, and the obstetrician under whose observation the children were first brought, had not been sufficiently taken into our confidence and taught to be on the lookout for choanal obstruction when the new born infant manifested evidences of impaired or deficient respiration. This form of deformity apparently affected the female sex more frequently than the male. The relative frequency of the bilateral to the unilateral was in the proportion of 3 to 1.

Richardson considered the condition from all standpoints, and especially dealt with the pathogenesis of the congenital occlusion of the posterior nares at considerable length, drawing attention to the fact that several views had been brought forward, none of which could be unconditionally accepted. He was of the opinion that the diagnosis of this condition was not attended with any difficulty if one only had the thought of the disturbance in mind. The prognosis of the new born child was distinctly a problem of life or death. The important problem which presented itself was as to whether it was better to attempt expectant treatment or resort to an immediate operation, but expectant treatment should never be attempted unless the parents were intelligent, willing to make the sacrifice of time, effort, and want of rest, and had a sufficient number of intelligent painstaking assistants. The best form of operation was then minutely described.

Dr. Dundas Grant in discussing the paper said that the condition when bilateral was rare. Possibly it passed unobserved, and the cases were included among those of asphyxia neonatorum. During ten years of considerable experience of midwifery he was convinced that he had never met with a case, but it was so serious when overlooked that the characteristics could not be too well known. He then read an account of a case given by Dr. Ronaldson, and published in *Edinburgh Medical Journal* in 1881, one of Lord Lister's earliest house

surgeons in Edinburgh. Grant described various operations for the condition, and particularly commended that devised by von Eicken. Regarding the asymmetry of the face which ought to follow congenital occlusion of the choanal referred to by Richardson, he could only say that when the late Mr. Cresswell Baker and he looked for the atrophy in their two cases they found that any trace of it which existed was on the wrong side.

Professor E. Schmiegelow of Copenhagen, Denmark, read a paper on the results of operation (laryngofissure) for intrinsic cancer of the larynx, and said, in part, that surgical treatment of intralaryngeal cancer gave exceedingly good results, especially when compared with those obtainable by surgical treatment of cancer in other internal organs. In his opinion the whole of our present knowledge of the diagnosis and treatment of this disease was founded on the work of Semon and Battin, who, towards the end of last century, entirely revolutionized our views with regard to the malignancy of intralaryngeal cancer. Before their day the surgical treatment of this disease had always been regarded as almost hopeless, but Semon showed us that the chief reason of this was that the disease was always diagnosed too late, so that it was too far advanced to give any good operative result. Having further learned that intralaryngeal cancer in the great majority of cases appeared as a primary cancer of the vocal cord, and therefore soon caused hoarseness, we had thus the means of recognizing the disease at an early stage of its development while still limited to the vocal cord, and so of a probable radical cure by removing the diseased vocal cord through a laryngofissure.

Having made the diagnosis by means of laryngoscopic inspection, supported by microscopic examination of a portion removed through the mouth, one had to remove the growth as soon as possible by means of a laryngofissure. This operation should be performed as indicated by Bullin and Semon, who, about 1890, inaugurated this treatment and proved that this comparatively safe operation was sufficient if only performed early enough. The operation should always be performed under general anesthesia.

Thyrotomy could only be performed in 33 of his cases treated up to 1913. The result of these 33 thyrotomies was that 28 patients survived the operation, while 5 died from pneumonia, due chiefly to postoperative hemorrhage. Among the 28 patients recurrence took place in 10 cases, while 18 patients were alive and well. The functional result was exceedingly good in all cases. The voice was strong, generally sonorous, but in a few cases hoarse.

Sir St. Clair Thomson in discussing this paper related his experience of the operation of laryngofissure, and pointed out that it was obvious that both the public and the medical profession in Denmark were more alert in discerning the conditions which could be relieved by operation than they were in England, as shown by the large number of opportunities afforded to Professor Schmiegelow. It was frequently the case in England that a patient would suffer from hoarseness, perhaps for a year before seeking the aid of a throat specialist. He was in favor of Professor Schmiegelow's teaching and technique *in toto*, preferring general anesthesia and preliminary tracheotomy. He removed the tracheotomy before the patient left the table, and got the patient out of bed as soon as possible. He remarked that in a series of seventeen operations for intrinsic cancer of the larynx he had had no unsuccessful cases, although one developed malignant disease of the parotid gland on the opposite side after seven years' immunity, clearly a new infection. As a rule, after the operation the voices were quite good, gradually becoming sonorous.

In none of his cases did thyrotomy reveal any error of diagnosis, although a preliminary microscopic examination of a removed portion was available in only six instances.

Dr. J. M. West of Baltimore read a paper on the intranasal surgery of the lacrymal apparatus after an experience of more than 225 operations. He described his technique for draining the lacrymal sac by establishing a permanent intranasal opening.

Dr. D. R. Paterson of Cardiff gave his experiences extending over nine months with cases of lacrymal stenosis, but refused to speak dogmatically of the permanency of the relief obtained, as all his cases were comparatively recent.

On Wednesday evening, July 29, Dr. Logan Turner of Edinburgh read a paper on the application of skiagraphy to the mastoid region and its use in the detection of disease which was discussed by Mr. Sidney Scott, London. Mr. Hugh E. Jones, Liverpool, read a paper on some considerations which determine the extent of an operation in septic invasion of the lateral sinus, which was discussed by Mr. Hunter Tod, London.

One of the most important and interesting sessions of the Congress was the symposium on the surgery of cleft palate held in the ballroom of the Savoy Hotel. On Thursday evening, July 30, the subject was introduced by Dr. George I. U. Brown, Milwaukee, who, after enumerating the operative procedures employed for the correction of cleft palate, stated that all operations should be directed to the attainment of these three objects: (1) To covering the gap; (2) to obtaining of speech, and (3) to improving general health. Therefore, the cautions to surgeons should be (1) to do no correcting methods where natural physiological development would obviate its need; (2) to destroy nothing that might be wanted in such development, and (3) to do no more than was wanted at each step. Consequently he condemned destruction of the premaxilla, and was critical of compression of the maxilla. He was of the opinion that the operation should begin with closure of the lip as early as the first day, to be followed by closure of the hard palate, and lastly of the soft palate, completing the case in one and a half to two years. He favored lateral incision to relieve tension when necessary.

Dr. Joseph Rilas Eastman of Galesburg, Ill., read a paper entitled "Factors of Safety in Cleft Palate Surgery." He described the Langenbeck and similar flap operations, and went on to say that general anesthesia was never of much value in cleft palate surgery, and with the present development of local anesthesia might be said to answer no valuable purpose. Elimination of the general anesthetic, and employment of local anesthesia removed many of the dangers of palate surgery, and added greatly to its simplicity. He pointed out that in extensive operations the swallowing of more or less blood was almost unavoidable. No matter what position was used or what precautions were taken, some blood was usually drawn into the stomach during the repair of cleft palate. After all extensive palate operation, the blood was sometimes discharged in vomitus, but more often it was passed off by the

bowel. The presence of this blood in the stomach of an infant or small child was not infrequently productive of serious disturbance of metabolism. The symptoms arose usually very soon after the deglutition of blood, sometimes within a few hours. The absorption of the pyrogenic constituents of a large quantity of blood quickly induced a high fever.

Observing infants after a cleft palate operation it had occurred to him that the degree of fever varied directly according to the severity and duration of the operation, that is, the more blood swallowed the greater the pyrexia. It was, of course, possible that the presence of the blood simply led to fermentation of other intestinal contents with consequent disturbance of metabolism, but, however, this might be, the fact seemed established that the blood in the stomach of an infant was either directly or indirectly thermogenic, and was therefore a serious menace because of the high fever which it might induce.

Referring to the mode and time of operation Eastman remarked that it was an old and quite generally accepted view that to operate for cleft palate on a child under the age of three months was unwise. This as Sir Arbuthnot Lane had stated was a matter of tradition. Eastman thought that there was little doubt but that surgeons who made it a rule to operate in the second or third year would have a lower mortality rate than those who operated early. The reason for this was not far to seek. Only the strongest survived the two or three years without early operation. The late operations therefore were good surgical risks. How large a percentage of those which were not operated upon early perished from disturbances of nutrition before the third year it would be difficult to estimate. It might be safely conjectured that the percentage was high. Many of such could be saved by early operation.

Dr. Truman W. Brophy, Chicago, insisted that the gap at birth was only potential; the normal amount of tissue was there and should be used immediately to close what is in effect a wound. By lead plate compression and tension wiring perfect speech was produced, and Dr. Brophy showed three patients on whom he had operated for different conditions and at different ages, the results being demonstrated by their delivery of recitations.

Sir W. Arbuthnot Lane said that he only claimed for his operative procedure for the correction of cleft palate perfect simplicity. He had convinced himself that the generally accepted practice of putting off operation for four years was dangerous, and he had therefore decided to close the cleff in the lips and hard palate at the earliest moment possible. He closed the cleft in the soft palate a month or so after the first operation. His mode of operation was based on the principle of restoring to the infant as quickly as possible opportunities for development of the bones of the face. Mr. James Berry of London held the view that operation by median suture was the only one which restored the palate to its normal condition. When done properly it gave the patient the best prospect of subsequent good speech. He preferred to operate at the earliest time at which the cleft could be satisfactorily closed by median suture. The time hinged largely on the nature of the cleft. Narrow clefts, especially if limited to the soft palate, could be operated upon within the first few months of life. The common, single or double, complete cleft associated with harelip should be treated by closure of the harelip in earliest infancy, the operation on the palate being postponed until the second or sometimes the third year. At and soon after birth the cleft was usually very wide and the palatine arch low. If any median operation were attempted at this period it would usually fail unless preceded by the wiring operation of Brophy, which he thought too dangerous to be generally employed. As for the turnover flap operation he entirely agreed with Sir Arbuthnot Lane with regard to its simplicity, as also with his statement that most mothers of cleft palate babies were exceedingly anxious that operation should be performed as early as possible. Berry criticised Lane for never having brought forward any proof that the ultimate results of such turnover operations were really good. Referring to lateral incisions, he employed them much less than formerly, as he found that the wide mattress stitch in the soft palate, similar to that used by Brophy for this part, often rendered them unnecessary.

Mr. Percy Legg of London closed the discussion, and particularly insisted upon the necessity for remembering that while the securing of good speech was the main object of all operative methods, speech could only become good by careful education.

On Friday evening, July 31, in the ballroom of the Savoy Hotel, a paper was read by Lt. Col. R. H. Elliott, I.M.S., Madras, India, on the sclerocorneal trephining operation for glaucoma. This paper was discussed by Mr. Treacher Collins of London. Mr. F. Richardson Cross of Bristol read a paper on operative procedure for strabismus which was discussed by Mr. N. Bishop Harman of London. Mr. J. B. Story of Dublin read a paper on operation for senile cataract, discussed by Mr. Holmes Spicer of London.

6. A Scheme for Promoting Efficiency in State Sanatoria. W. C. Bailey and C. C. MacCorison.

2. Pyogenic Infections of the Upper Urinary Tract.—A. L. Chute states that the diagnosis of the pyogenic infections of the upper urinary tract often presents much that is confusing. In the acute stage, if the swelling of the kidney tissue is enough to cause pressure on the capsule, there are pain and tenderness as well as temperature—usually the temperature is rather out of proportion to the apparent illness of the patient. Often, if the invasion is not very acute, there is little to localize the process and exceptionally it may be recognized only by the condition of the urine. This is especially likely to happen with young children when the question of an acute renal infection must always be considered in a patient presenting an indefinite illness with temperature. In the chronic renal suppurations—not alone the cases of pyelonephritis—but where there are abscess cavities, or even pyonephrotic sacs, provided the pus is not under tension, there are often no symptoms that point to the renal origin of the process. What subjective symptoms there are may, in fact, point more to the bladder than to the kidney. The sure way of diagnosis is the catheterization of the ureters. It allows not alone the localization of the suppuration, but the differentiation between kidneys showing foci of suppuration and kidneys that have

been turned into pyonephrosis so advanced that there is little secretion of water. In the same way collecting a urine from the ureter (not the kidney pelvis) of a suppurating kidney will give a very fair idea of the secretion and consequently of the extent to which the suppuration has destroyed its function. The application of the phenolsulphonaphthalein, and the indigo-carmine tests accomplishes the same results. The underlying principle for the treatment of the chronic infections is the securing of adequate drainage, in the cases where conservative treatment is possible. This consists in the simplest instances in freeing abnormally tied-down organs or in fastening in place abnormally mobile ones. In other instances it consists in doing plastics of various sorts. The object is to secure perfect drainage of the infected kidney. The result gotten in some of these cases of renal suppuration is gratifying even in cases that were unpromising; on the whole, however, the author's experience with conservative operations on kidneys that have shown definite foci of chronic suppuration, has not been very encouraging. The removal of a suppurating kidney in the presence of a well fellow is attended with such brilliant results that the author thinks one tends toward the radical operation. It is fair to expect, however, that one's increasing knowledge of the subject will lead in the future to more satisfactory results from conservative operations upon suppurating kidneys.

3. **Treatment of Movable Kidney, with or without Infection, by Posture.**—H. Cabot and L. T. Brown call attention to a certain type of individual having a body type with which ptosis in its various forms is commonly associated. Of this ptosis mobility of the kidney is a part. Obstruction of the ureter is at least a very important cause of renal infection. Many of these patients come to the surgeon on account of symptoms chiefly referable to the kidney and many of them have a pyelitis with more or less tendency to relapse. The fixing of these kidneys by surgical measures is sometimes a most effective measure but should it be possible to limit the mobility of the kidney by other means it is obviously desirable. The work done by Goldthwait and his colleagues suggests that considerable benefit may be obtained by alterations in posture and the authors' work has been in the determination of the effect upon these kidneys of alteration of posture similar to that suggested by Goldthwait. One of their patients was a woman in whom the symptoms were that she had much weakness in the abdomen with the result that it was impossible for her to sit up for long. There was much backache low down and at the back of neck and much abdominal pain. Four years ago the right kidney was hitched up and the appendix removed. These operations were performed for pain in the right side of abdomen. After this she was better for two years when she developed neuralgia in the left chest and then shingles on the left side. Since then the abdominal pain has returned and increased. The nights were bad. Digestion was poor. Vomiting occurred at times with much gas. The treatment was planned to change the shape of the body from the very cramped and poorly functioning condition. The hope was that as the body changed its shape there would come a readjustment of the abdominal organs which would allow them to functionate better.

4. **X-Ray Determination of Renal and Ureteric Variations.**—P. Brown divides the renal and ureteric abnormalities, in which the *x*-rays have proven to be a diagnostic factor into enlargements of the renal viscus, with but secondary reference to its pelvis; dilatations of the renal pelvis, with no especial reference to the general interstitial tissue; and a combination of renal enlargement and pelvic dilatation. The specific causes of such abnormal phenomena as usually seen by the roentgenologist as: hypertrophies from compensatory change; hypertrophies and dilatations from hydronephrotic change; hypertrophies and dilatations from change due to malignancy, such as the hypernephromata, etc.; and hypertrophies, with or without degeneration, from changes pyonephrotic or cystic.

5. **The Early Diagnosis and Treatment of Manic Depression.**—A. H. Ring notes that there are two somewhat typical ways in which the acute condition may come on: the first sudden, the second gradual. In cases of sudden onset the doctor is frequently not called until mental symptoms predominate; but it is not uncommon to learn that these patients have been treated for a week or more for acute indigestion, and have been known not to be well for two or three months. After memory has been prodded the family will say that they now realize that for a year or more the patient has not been himself but they never suspected anything of this sort. In the second type, *i. e.* those of gradual onset, the mental symptoms do not become marked for some time, the physical symptoms predominating. Most commonly the patients come under treatment for digestive disorders, liver trouble, and the like. There is, perhaps, no single psychosis which occurs with such frequency. Diefendorf says it constitutes from 12 to 20 per cent. of admissions to insane hospitals. In its early state there is no psychosis which so commonly goes unrecognized; it is tagged "just nervousness," "the blues," neurasthenia, or even as hysteria, and it frequently does not get beyond this mild form. Because of the mildness of its early symptoms and the slight degree to which the intellect is involved at first, its victims form by far the larger part of the so-called borderline psychoses. In the more severe forms with persistent insomnia, great elation or depression, and anomalies of nervous (volitional) control (excessive rapidity or retardation), it is easy enough to recognize manic depression, especially if accompanied by hallucinations or delusions. The preponderance of symptoms of manic depression are somatic. Whether of the depressive, manic, or the mixed phase it manifests itself mentally as a disturbance of the feeling, psychologically expressed as an exaggeration of the sense of pleasantness and unpleasantness. These patients frequently realize the mental disturbance before it is objectively evident. To this extent the personality is disturbed; but the patient can, if he exerts himself, in the early stage tell one that he knows the change is in himself, thus distinguishing his condition from dementia præcox, in which the patient insists that he is all right, but is abused by people or things outside him. This is not so true of the more advanced stage.

6. **Efficiency in State Sanatoria.**—W. C. Bailey and C. C. MacCorison point out that in one State sanatorium studied by them particularly not only was there almost no coöperation on the part of the patients, but an actual systematized antagonism against the efforts of the physician was found to exist. To put an end to this condition of affairs a fundamental working scheme was evolved. The patients were to divide themselves into two voluntary classes. The first was to be called the "sanatorium class," and here would group themselves those patients who really wished to get well, who would coöperate with and aid the senatorium management in every way, who would help others in the institution and who, when they left, would still keep up the fight and would get their societies and unions to study the problem and help to solve it. In the other class, to be called the "hospital class," were those who did not care particularly about their own health or that of others, who did not care to obey rules,

who did not want to coöperate, but simply used the sanatorium as a boarding-house. They were told that the regime for the sanatorium class was to be a strict one; but that the results would prove that it was for their benefit, and that from time to time the gain of those in the sanatorium class over those in the hospital class would be tabulated and furnished to the patients. The immediate results noted following the inauguration of this plan were a decrease in hemorrhages, pleurisies, and fevers, with an attendant falling off in orders for medicine special diets, and raw eggs. There was also a marked decrease in the number of needless complaints and fault-findings; in short there was established an esprit de corps. There followed week by week a marked increase in amount of weight gained, until the record for all the years has been surpassed by many hundred pounds.

1. Carbolic Instillation in the Treatment of Bladder Tuberculosis.—E. L. Keyes, Jr., states that local treatment is occasionally and brilliantly effective in relieving the painful symptoms of bladder tuberculosis. Three principles that must be recognized in the treatment of such cases are: (1) The instrument must not enter the bladder. There are cases of isolated ulceration about the ureter orifice or fundus that may be treated successfully by fulguration for example but such cases are extremely rare. Usually the tuberculosis involves the trigonum up to the bladder neck, and the sensitiveness of this must be respected. (2) The bladder must not be distended. Here there are no exceptions. (3) The injection must give relief in proportion to the pain it inflicts. The following drugs have been used by the author for the relief of the symptoms of bladder tuberculosis: Thalline, gomenol, bichloride of mercury, and carbolic acid. Thalline sulphate is not very irritating. A saturated solution in water contains twenty per cent. of the drug and is much less irritating than a one to 1,000 solution of silver nitrate. The author has used it in strengths varying from three to twenty per cent. It usually gives no relief whatever; yet occasionally it is efficacious. Gomenol, though greatly praised by some, has in the author's hands achieved no more brilliant results than those obtained from thalline. As a rule it has not seemed peculiarly efficacious. Bichloride of mercury, on the other hand, has been of great service to the author in the treatment of these patients. It must of course be employed, as an instillation, not as an irrigation. The initial dose should not exceed a strength of one to 20,000 parts of water. Repeating the installation daily and increasing the strength rapidly, so long as the patient does not complain of any grave irritation one soon reaches the strength of one part bichloride to five or ten thousand of water. Carbolic acid acts when the foregoing fail. Rovsing suggested the use of this acid for the treatment of bladder tuberculosis, but no one has been able to achieve with Rovsing's method the success announced for it by its distinguished sponsor. He employs an irrigation of carbolic acid in five per cent. solution. He states that this solution should be injected into the bladder and permitted to flow out again, again reinjected, and so on, until the solution no longer returns smoky. The amount injected approximates the bladder capacity. One may safely begin with a solution of one to 200 of water and rapidly increase this to one per cent. before the patient complains of an increase in pain.

3. Abdominal Incisions.—M. J. Horan, as the result of experiments on the cadaver concludes that in some of the abdominal incisions, especially those of the right rectus, there is no apparent injury to the incision with a pressure of 120 pounds. In the incisions of the median line above the umbilicus, no apparent damage is done by high intraabdominal pressure. Median line incisions below the umbilicus give way under pressure of 20 pounds in one case, and forty pounds in another. Incisions over McBurney's point yields to less than twenty pounds pressure in some cases, especially those in which the air is introduced in the rectum. The deduction is that intraabdominal pressure is not alone the cause of hernia following any abdominal operation, as some of the abdomens were more tense with sixty pounds pressure than any seen by the writer after any operation.

4. Diagnostic Aids in Diseases of Bones and Joints.—H. Keller states that in order to make a proper diagnosis in disease of bones and joints, it is necessary to ransack every accessible part of the body in order to locate the cause of the infection; tonsils, teeth, and gums should be thoroughly inspected, the urine and feces should be analyzed carefully, and the organs of generation should be thoroughly examined. After one has found germs which look suspicious, one should do his utmost to ascertain by scientific means whether or not this germ is the sole cause of the trouble or a contributing factor only. Radiography is at once the best means at one's disposal for verifying clinical findings, provided the surgeon bears in mind the following facts: (1) If the *x*-ray is negative and the clinical signs are definite, one should depend upon clinical signs; (2) if the clinical signs are indefinite while the *x*-ray findings are definite, one should bear these findings in mind, but make sure that the plate has been taken by an expert on *x*-ray pictures, that the part has received the proper exposure, and that the plate has been properly developed; (3) no surgeon should depend solely upon the radiologist for the interpretation of findings in the plate; (4) it is always advisable to take anteroposterior and lateral views in diseases or injuries of bones and joints, in order to bring out all the features of the disease; (5) in order to recognize an injury or a disease around the joint, especially in young individuals, it is necessary to remember the time of development and ossification of the epiphyses; (6) plaster of Paris is permeable to the rays, while zinc oxide plaster usually mars the clearness of the shadow, and should never be applied to the part to be *x*-rayed; (7) it is always necessary to take a picture of the joint on the opposite side in order to be able to detect the slightest deviations from the normal; (8) there are times when cracks are seen and are interpreted by some as fractures, but they are no more than defects in the plate due to some unexplainable cause. The blood examination includes the complement deviation tests. In tuberculous disease of bone the coagulation time of the blood is usually prolonged (between six and seven minutes), also in those cases of arthritis in which coagulation time of the blood was below three minutes, the injection of pituitary extract hypodermically seems to have a beneficial effect. Tuberculin injections for diagnostic purposes are condemned; the focal reaction following injection of tuberculin is such as to be contraindicated in joint diseases. The author has investigated the power of absorption in joints in a

healthy state and has compared their absorptive power with that of other parts of the body and with that of diseased joints. Injecting one cubic centimeter of phenolsulphonaphthalein into the normal joint, and noting the time of its appearance in the urine by the addition of sodium hydrate solution, and then a day later giving an intramuscular injection of the same drug, and also noting the time of appearance of the drug in the urine, the absorptive power of the normal joint could be compared with the systemic absorption. By injecting one cubic centmeter of the same drug into the diseased joint and noting the time of the appearance of the phenosulphonephthalein in the urine after injecting the drug into the diseased joint and into the healthy one, one can tell the difference of the absorptive function of the two joints. The experiments showed that the normal joints have the same absorption time as the muscular region; that in long standing synovial disease, the absorption time may be prolonged even up to double the normal time; and that in early cases of diseases of the joint, one may find that the absorption time in the diseased joint is hastened compared to the normal one.

7. **The Tonsil from a Surgical Viewpoint.**—M. Lubman concludes that the tonsil has not participated to any great extent in the progress of surgery during the twentieth century. Whether it is a disease carrier and is sacrificed to human welfare, or whether it is a functionating organ and is enucleated as a martyr to ignorance, one can be certain that the average handling of the tonsils is reckless, unscientific, and inhuman. Upon examining the many evil effects which result from our operation at present, one is tempted to ask if the game is really worth the candle. Indeed, the tonsil occupies an open position, easy of access; and the operation is still further simplified by the instruments now at one's command; but this does not justify the crude and inhuman attitude toward patients, even to the extent of sparing an anesthetic. It is time for the medical profession to include the tonsil operation in the field of major surgery; by doing so one may hope that the tonsil operations will be considered more seriously, and invite all due caution; and this may eventually lead to a universal agreement as to the function of the tonsil and may produce excellent surgical methods.

8. **Immunity in Measles.**—C. S. Woods calls attention to the apparent result of Hektoen's success in producing experimental measles as indicating beyond a doubt that measles may be transmitted by injecting the blood of a person having measles into another person in normal health. He relates an instance in which a woman in the eighth month of pregnancy contracted measles. The child, while in utero, must have had an ideal opportunity to acquire immunity against this disease. The child, however, now seven years old, had an attack of measles this spring. This emphasises the great difficulty of securing immunity and the power of the virus of measles to invade the human organism.

9. **Retroperitoneal Hernia.**—A. Primrose reports a case of retroperitoneal hernia which he regards as possibly unique, occurring as it does in connection with an extremely rare abnormality, namely, the existence of an aberrant origin and course of the middle colic artery which rose from the right iliac artery and passed upward to its destination to the transverse colon, forming a peritoneal pouch which contained the whole of the small intestine. The case is also of interest because while apparently all other cases hitherto recorded were either found accidentally post-mortem, or in operations caused by symptoms of the hernia, in this case the operation was done for gastric symptoms and the retroperitoneal hernia had given rise to no symptoms except a slight ileostenosis as revealed by the *x*-rays. The author notes that most cases of retroperitoneal hernia have a very intimate relation to the course of some particular blood vessel which becomes somewhat abnormally developed during fetal life and produces folds of peritonium and certain fossæ connected with these folds. It is important to note the relation of these blood vessels to the neck of the sac, as in operating for strangulation they might become severed and imperil the nutrition of a large section of intestine.

10. **The Hemiopic Pupillary Reaction.**—C. B. Walker draws the following conclusions: A weak hemiopic pupillary reaction may be masked by the pupillometer light when observed consensually. Light and dark adaptive phenomena, in addition to dispersion light, seriously complicate the hemiopic pupillary reaction. The hemiopic pupillary reaction is definitely present in anterior lesions, when examined by the rotary shutter method. The hemiopic pupillary reaction is also present in cases having every clinical evidence of being purely posterior cases, although necropsy examination is necessary to prove absolutely that there is no involvement of the optic tract or primary ganglion centers. Although it may be concluded from the examination of these cases that the peripheral retina does possess a weak pupilomotor sensitiveness, there is no evidence that the hemiopic pupillary reaction has any topical diagnostic value.

12. **Active Immunization in Diphtheria and Treatment by Toxin-Antitoxin.**—W. H. Park and A. Zingher, assisted by M. H. Serota, conclude that those who are definitely exposed to infection should be passively im-

munized even if the toxin-antitoxin injections have been given. The use of the Schick test eliminates the necessity of immunizing about two-thirds of those subjected to exposure, as, judging from a year's experience, those not reacting are immune. Those found to be naturally immune probably continue immune for a considerable period of time, possibly indefinitely. Active immunization is indicated when there is no immediate danger of infection and when it is desirable to lessen the number of susceptible persons. It is too early to decide whether active immunization should be attempted on a large scale. The lack of a sufficient response in at least 50 per cent. of those susceptible to diphtheria and the fact that the immunity lasts for but one or two years are drawbacks that will probably limit to some degree the usefulness of this procedure.

1. Heredity.—W. Bateson presents an account of the discoveries made by Mendelian or analytical methods of study and the deductions which these physiological facts suggest in application both to evolutionary theory at large and to the special case of the natural history of human society. The recognition of the significance of heredity is modern. The term itself in its scientific sense is no older than Herbert Spencer. Historians debate the past of the human species and statesmen order its present or profess to guide its future as if the animal man, the unit of their calculations, with his vast diversity of powers, were a homogeneous material which can be multiplied like shot. The reason for this neglect lies in ignorance and misunderstanding of the nature of variation; for not until the fact of congenital diversity is grasped with all that it imports, does knowledge of the system of hereditary transmission stand out as a primary necessity in the construction of any theory of evolution, or any scheme of human polity. Darwin was the first to provide a body of fact demonstrating the variability of living things, whatever be its causation. Formerly it was hoped that by the simple inspection of embryological processes the modes of heredity might be ascertained. For the old methods of attack there has been substituted the breaking up of the main problem into its parts, such analytical study being called Mendelian because Mendel was the first to apply it. The allotment of characteristics among offspring is not accomplished by the exudation of drops of a tincture representing the sum of the characteristics of the parent organism, but by a process of cell-division, in which numbers of these characters or rather the elements upon which they depend, are sorted out among the resulting germ cells in an orderly fashion. Analytical breeding proves that it is according to the distribution of these genetic factors, to use a non-committal term, that the characters of the offspring are decided. The great differences which characterize distinct species are due generally to such independent factors, the essential principle being that an organism cannot pass on to its offspring a factor which it has not itself received in fertilization. Parents who are both destitute of a given factor can only produce offspring equally destitute of it, and parents both pure-bred for the presence of a factor produce offspring equally pure-bred for its presence. Whereas the germ cells of the pure-bred are all alike, those of the cross-bred, owing to the union of dissimilar germ cells are mixed in character. Each positive factor segregrates from its negative opposite, so that some germ cells carry the factor and some do not. Once the factors have been identified by their effects the average composition of the several kinds of families formed from the various matings can be predicted. In face of what one now knows of the distribution of variability in Nature the scope claimed for natural selection in determining the fixity of species must be greatly reduced. The doctrine of the survival of the fittest is undeniable as long as it is applied to the organism as a whole, but to attempt by this principle to find value in all definiteness of parts and functions, and in the name of science to see fitness everywhere is mere eighteenth century optimism. The appearance of contemporary variability proves to be an illusion. Variation from step to step in the series must occur either by the addition or by the loss of a factor. Of the origin of new forms by loss there seems to the author to be fairly clear evidence, but of the contemporary acquisition of any new factor there is no satisfactory proof. Variation now stands out as a definite physiological event. The notion has been abandoned that large differences can arise by the accumulation of small differences. Such small differences are often mere ephemeral effects of conditions of life, and as such are not transmissible; but even small differences, when truly genetic, are factorial like the larger ones, and there is not the slightest reason for supposing that they are capable of summation. There is evidence for disbelieving in the common theory that domestic animals have been developed from a few wild types. It is hopeless to reconstruct the steps in evolution of various forms of fowls from the Indian jungle fowl, while most of the new varieties of cultivated plants are the outcome of deliberate crossing. One cannot often actually prove variation by loss of factor to be a real phenomenon. Though one may have to forego a plan of variations by addition of factors, variation both by loss of factors and fractionation of factors is a genuine phenomenon of contemporary nature. That primordial life may have been of small dimensions need not disturb one. Quantity is of no account in these considerations. Shakespeare once existed as a speck of protoplasm not so big as a small pin's head. To this nothing was added that would not equally well have served to build up a babboon or a rat. The artistic gifts of mankind will prove to be due, not to something added to the make-up of an ordinary man, but to the absence of factors which in the normal person inhibit the development of these gifts. They are almost beyond doubt to be looked upon as releases of powers normally suppressed. The instrument is there, but it is "stopped down." The scents of flowers or fruits, the finely repeated divisions that give its quality to the wool of the merino, or in an analogous case the multiplicity of quills to the tail of the fantail pigeon, are in all probability other examples of such releases. In spite of seeming perversity, therefore, one has to admit that there is no evolutionary change which in the present state of one's knowledge one can positively declare to be not due to loss. Modern research lends not the smallest encouragement or sanction to the view that gradual evolution occurs by the transformation of masses of individuals, though that fancy has fixed itself on popular imagination. The isolated events to which variation is due are evidently changes in the germinal tissues, probably in the manner in which they divide. It is likely that the occurrence of these variations is wholly irregular, and as to their causation one

is absolutely without surmise or even plausible speculation. Distinct types once arisen, no doubt a profusion of the forms called species have been derived from them by simple crossing and subsequent recombination.

2. **Congenital Atresia of the Postnasal Orifice.**—C. W. Richardson states that congenital atresia is that form of obstruction of the postnasal orific that takes place in utero, the result of a misplacement or other malformation in the embryo, not in any way due to inflammatory reaction or pressure, and usually characterized by a more or less complete partition, obstructing one or both postnasal orifices. In considering the pathogenesis of the congenital occlusion of the posterior nares there are several views to consider, no one of which can one unconditionally accept. (1) Luschka considers the obstructing plate to be a projection upward and backward of the horizontal plate of the palate bone. (2) The Kundrat theory holds that the obstruction is due to an extension inward of the vertical plates of the palate bones. According to this view the vertical plates of the palate extend inward until they reach the inner wall of the choanal orific, and when occurring bilaterally they unite with their fellow of the opposite side, the vomer being received between the two plates. (3) According to Hopmann, the choanal obstruction is an extreme degree of the occasionally observed choanal asymmetry. The narrow groove which is often seen on the posterior surface of the diaphragm is the remaining evidence of the originally existing postnasal orifice. (4) The opinion advanced by Bitot holds that the plate forming the partition is a separate independent bone, as indicated by the separate sutures evidenced therein. Symptoms of congenital choanal obstruction may be divided into those as manifested in the newborn child and those existing in patients observed first at a later period in life. In the newborn child with bilateral obstruction the all-pervading symptom is the abolition of nasal breathing, with the train of symptoms produced thereby. The infant, not being able to breath through the nose, becomes rapidly cyanosed until the discomfort is so great as to cause it to cry when the air hunger is relieved through the momentarily established mouth breathing, and the thus threatening asphyxia is relieved. As the relief comes through mouth breathing the child ceases to cry, and there are a few seconds of quietude, when the desire for air again becomes rapidly great, the lips are drawn tight and cheeks drawn in, and then a struggle results, as is usually manifested by one who is suffering greatly from the want of air, the face becoming more and more cyanosed, when the child again breaks out with a lusty cry, which again relieves the threatening asphyxia through mouth-inhaling air. In older children and adults with congenital choanal obstruction the absence of nasal respiration is the pronounced symptom. In bilateral obstruction this is complete; in unilateral obstruction it is incomplete and limited to the side affected. The obstructed nasal chamber is always filled with a thick albuminous mucous. Examination reveals usually a widening of the nasal chambers. In unilateral cases the septum is frequently, not always, deflected toward the obstructed side. In infants the tendency to develop marasmus through deficiency or inability to maintain nutrition is very great. The prognosis in the older child who has passed through the suckling period is extremely favorable as to the probable result of operative intervention. The prognosis in the newborn child is distinctly a problem of life or death. The important problem which presents itself here is as to whether it is better to attempt expectant treatment or resort to an immediate operation. Expectant treatment should never be attempted unless the parents are inteligent and the infant is also a well-nourished, strong, and healthy child. The feeding must be resorted to through the medium of a spoon. It is remarkable how quickly the child learns voluntarily to establish mouth-breathing within ten days, and also learns to suck from a bottle within three weeks. The factors in favor of the operation, should it be successful, are the immediate relief to the sufferer, its ability to breathe and take nourishment normally almost immediately thereafter, and the great pleasure to the parents. In the older child and adults, as in the infant, the only procedure that offers any relief is operative intervention. Various operative procedures have been suggested and done for the relief of this deformity. In a general way that procedure is best which is accompanied by the least injury and accomplishes the result most thoroughly. The chisel to penetrate the plate along the line of attachment of the vomer and the various forms of conchotomes to remove the remaining portion of the obstructing plate seem the ideal methods of dealing with the condition under consideration. This procedure should be done with the finger in the nasopharynx as a protector and guide.

3. **Pregnancy Complicated by Severe Morbus Cordis.**—J. Bright Banister reports two cases of pregnancy complicated by severe heart disease with broken compensation in which hysterotomy was performed under spinal anesthesia. The author feels strongly that patients with marked cardiac lesions should not be allowed to incur the risks of repeated pregnancies, as increasing experience has convinced the author that though the immediate danger is not excessive their expectation of life is materially shortened by the strain of repeated pregnancies. In the combination of spinal anesthesia and hysterotomy, vaginal up to the twenty-fourth week, abdominal at a later date, the author feels that there is a method of treatment for these cases which is both rapid and efficient, and at least worthy of consideration.

4. **Gun Deafness and Its Prevention.**—By Jobson Horne. (See page 425.)

Cerebellar Abscess; Operation; Recovery.—W. Milligan reports the case of a male aged 15 years, who was first admitted to the Royal Infirmary, Manchester, April, 1909, with both ears discharging. Radical operation upon right ear; local treatment advised for left ear. Readmitted November 10, 1913. Right ear perfectly well; antrotympanic cavity completely epidermized. For past three weeks had complained of severe headache, mainly frontal. Had felt sick but had not vomited until day before admission. Had been very constipated. Patient quite rational, but cerebration slow. Temperature, 98.2° F., pulse 66, respiration 18. No paralysis. Knee-jerks exaggerated, equal. No Babinski. Marked ataxia. Tendency to fall forward. Dysdiadochokinesis present. Pupils equal and dilated. Optic neuritis (?). Nystagmus on looking to left (affected side). Left auditory meatus full of dense polypoid tissue and pus. It was impossible, therefore, to make a complete labyrinthine examination. Diagnosis: Left cerebellar abscess. Previous to operation 4 drams of cerebrospinal fluid were withdrawn; it was clear and under pressure. Operation: Radical mastoid. Opening made through posterior wall of antrum; cerebellar dura exposed; incised. An abscess containing a little over ½ ounce of pus was evacuated. Drainage by means of rubber tube. Bacteriological examination: Almost a pure streptococcal infection; a few staphylococci present.—*Proceedings of the Royal Society of Medicine.*

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

ADVERSE LEGISLATION AFFECTING THE INTERESTS OF LIFE INSURANCE.

A CONSCIENTIOUS, conservative, and efficient regulation of life insurance companies by the State authorities creates a feeling of confidence and security among the policyholders. Unfortunately, the history of life insurance shows that the overzealous lawmakers have not always been content with the making of beneficial provisions, and, losing sight of the fact that these institutions are not great money-making corporations, have been far too anxious and energetic in forcing the passage of measures depriving the policyholders of benefits and privileges to which they are entitled. The medical examiners throughout the entire country are in a position to help largely in molding public opinion and thereby compel office-seeking politicians to give more consideration to the best interests of their constituents. The examiners will find that many members of their respective communities have not given any thought to the subject and that an intelligent explanation of the bearing of burdensome laws affecting their interests as policyholders will be appreciated. It should be made clear to them that the only source of income to their companies for the payment of claims and dividends is the premiums and the interest earned thereon, and that the gains and savings are subsequently returned to the policyholders in the form of so-called "dividends." Every demand for funds from a company, whether fair or unreasonable, means that these dividends will be just so much lower.

Life insurance companies bear too heavy a burden of taxation. One single large company paid $1,333,534 in direct taxes in 1912, of which $233,187 represented the United States corporation tax, and most of the balance went to the various states. It is proper for life insurance companies to contribute their share toward the support of the government under the protection of whose laws they do business, but this is fully carried out by the usual taxation of the properties in which the insurance funds are invested. An additional tax, however, on funds belonging to policyholders or on premiums paid by them, especially in mutual concerns, cannot be defended on economic principles, since it penalizes thrift, foresight and prudence. Referring to taxation on premiums, it has been said: "This is America's great burden on thrift and providence, and is a rapidly increasing evil, directly affecting twenty-five million of our people. America, alone of all governments in the world, so taxes life insurance."

Wise and sensible laws for the regulation of investments by life insurance companies act as additional safeguards and have a salutary effect. On the other hand, noxious and burdensome legislative measures have driven most foreign companies from certain countries and states. These demands were partly incited by a desire to eliminate healthy competition with the home companies. Prussia in 1895, and France in 1906, established laws, the general drift of which was to require the deposit of all reserves of policies written in each country to be invested in the securities of that country and deposited with its government. The American companies transacting business in these countries were earning over 4 per cent. on investments in America, while 3 per cent. was the highest that could be expected on the reserves invested in European securities. In order to continue business, therefore, it would have been necessary to conduct a separate system of book-keeping and a complicated special accounting for the foreign policies, an arrangement which was considered wasteful by some companies, so they withdrew promptly. The wisdom of refusing to submit to these demands in countries where trouble was always brewing, and conditions would be so far beyond control of the American offices, is vindicated at the present time. One large company which remained is reported to have reserves amounting to $85,000,000 invested in European securities which must surely depreciate, and this loss, with the destruction of life in the great war now raging, will surely encroach heavily upon the savings of the company for policyholders at home.

Examples of hasty, ill-considered legislation abound among the acts of some of our own forty-six state governments. One state put a statute on its books which required the investment of 75 per cent. of the reserves of policies written in that state in the securities of that state, and, also, the deposit of this reserve within the state, where it would be subject to a local tax of 3 per cent. Every company must make at least 3 per cent. on its investments to maintain its reserve, so that submission to the demand of this state would mean that the company would have to earn at least 6 per cent. on its investments, an impossibility with first-class securities. Furthermore, if all the companies doing business at the time had remained, the state could not have furnished sufficient high-grade securities to absorb the reserves. An attempt has been made to modify the laws, but it has not been sufficiently successful so far to attract the sound and important companies which withdrew. Another state made it mandatory for all companies transacting business within its boundaries to make an annual accounting to each policyholder in regard to his individual share in the reserve and contingency funds. This requirement could only be accomplished by endless trouble and at great additional expense to policyholders outside as well as inside the said state, and nearly every prominent company, therefore, withdrew. This same state, according to Frick (*American Underwriter*, Nov., 1913), has established a state life fund. The following comparison exhibits the less advantageous terms usually obtained from government enterprises. The premium charged by the state life fund in 1912 for a $1,000 twenty-payment policy, age 29, was $30.57, no tax. For the same policy, issued by a well-known mutual company in the same state, the premium is $32.83, but if the tax and costs amounting to $5.35, imposed upon it by the state, is deducted, a premium of only $27.48 remains. Another state does not allow the suicide clause to stand unless it can be proved that the policyholder, committing suicide, accepted the policy with the deliberate intention of taking his life. To meet such a condition an affidavit would have to be secured from the applicant before the policy is given to him to the effect that he is contemplating suicide, an obviously ridiculous practice in the business of life insurance.

Many other illustrations could be shown to demonstrate why the public should safeguard the interests of life insurance companies for the mere sake of protecting its own interests.

Society Reports.

AMERICAN GASTROENTEROLOGICAL ASSOCIATION.

Seventeenth Annual Meeting, Held at Atlantic City, N. J., June 22-23, 1914.

Lymphocytosis as a Sign of Constitutional Derangement in Chronic Diseases of the Digestive Tract.—Dr. J. KAUFMANN of New York City, after an exhaustive study of the subject, came to the conclusion that the most important lesson to be learned from it was that the constitutional factor so often found at the bottom of gastrointestinal disorders should receive full consideration in the treatment of such cases. He considered the anatomical lesions as merely the end results of these conditions. The avoidance of recurrences would, he thought, depend on the ability of the physician to regulate the patient's mode of living, rather than on the ability of the patient to observe general hygienic and dietetic rules.

Aerophagy.—Dr. CHARLES D. AARON of Detroit, Mich., contended that continued belching of gas for a considerable length of time would indicate aerophagy, and said that the eructated gas consisted, in the main, of atmospheric air swallowed in attempting to belch. Aerophagy accompanied many neuroses, he said, and was a frequent symptom of functional and organic disease of the gastrointestinal tract. He considered the presence of bile in the gastric content, with eructation, as suggestive of aerophagy.

Dr. JOHN C. HEMMETER of Baltimore stated that all the gas eructated was not air, but that a great deal of carbon dioxide was with it, this being obtained from the saliva.

Dr. JOHN P. SAWYER of Cleveland, Ohio, said that the patients could easily be instructed as how to avoid the descent of the diaphragm when belching, and the consequent pumping of air into their stomachs.

Dr. JOHN A. LICHTY of Pittsburg, Pa., asked whether the swallowing of air was the only cause of acute dilatation of the stomach.

Dr. AARON replied that it was not, but that it was one of the factors in its production.

Dr. JOS. C. BLOODGOOD of Baltimore remembered to have had only one such case, in which he had passed the stomach tube and obtained no fluid.

Dr. SAWYER remarked that aerophagy should not be confused with acute dilatation of the stomach.

Dr. KAUFMANN said that gas could get into the stomach in several ways, other than by the swallowing of air and saliva. It could be produced by fermentation in the stomach and could enter the stomach from the blood.

Dr. AARON said, in closing the discussion, that aerophagy was found in almost every disease of the stomach.

Linitis Plastica.—Dr. JOSEPH SAILER of Philadelphia gave an account of an interesting case of this condition, and said that a patulous stomach, like this one, was very unusual. An exploratory operation was performed. It was found that the growth extended from the pylorus to the fundus. As the case had progressed unfavorably after this, the growth involving practically the whole of the fundus, Dr. Sailer expected to have a more radical operation performed later.

Dr. JULIUS FRIEDENWALD of Baltimore mentioned having reported a similar case to the society about fourteen years ago. It had been thought to be cancer in the beginning, but a microscopic examination of the stomach showed that it was not. The patient died a few days after the operation.

Dr. FRANK SMITHIES of Rochester, Minn., asked Dr. Sailer whether the Wassermann or Abderhalden test had been made in his patient's case. The speaker thought that a leather-bottle stomach, produced by interstitial syphilis, might resemble linitis plastica.

Dr. CHARLES G. STOCKTON of Buffalo, N. Y., called attention to the fact that cases of linitis plastica sometimes resembled cardiospasm in their symptomatology.

Dr. BLOODGOOD was of the opinion that linitis plastica was really a diffuse ulceration of the stomach. The mucous membrane was gone, although the surface looked as if it were there because it was of the same color.

Dr. SAILER said that the Wassermann had been made in this case and found negative. He thought that the fact that there was a type of chronic interstitial gastritis was proved by there being cases on record that were apparently in perfect health from three to five years after operation. These could not have been cancer of the stomach.

Some Observations on Achylia Gastrica and Achlorhydria.—Dr. THOMAS R. BROWN of Baltimore, in his paper, discussed certain of the rarer conditions in which achylia gastrica is met. He then took up the estimation of pepsin in achylia gastrica, and was struck with the fact that in all but one case examined pepsin was practically absent, although these cases were taken indiscriminately and included various conditions. The Wolff-Junghans test was also made, and was found valuable in differentiating carcinoma from non-malignant achylia gastrica. The fourth point considered by the author referred to the study of the stools. He made a careful quantitative determination of the diastatic ferment, finding a normal amount, in seven of the eight cases examined.

Dr. SMITHIES said that in cases in which free hydrochloric acid was absent it was common to consider them as cases of achylia gastrica; but that one should endeavor to find what other factor was associated with the achylia, if achylia was present. He had made over seven hundred Wolff-Jughans tests in cases in which achylia was present or a suspicion of carcinoma, and his results had been quite comparable to those of Dr. Brown.

Dr. LICHTY remarked that some of the achylias found in cases of infectious disease were but temporary. He believed that pain and nervous shock might have an effect on the gastric secretion; as in one patient in whom hyperchlorhydria was common he had found achylia present after a nervous shock.

Dr. MAX EINHORN of New York City had noticed that achylia gastrica was frequently present in arthritis deformans. As a rule the total acidity was low in cases of true achylia, he said; while in cases of carcinoma it would never be low. He considered the biuret test as important as some of the newer tests.

Dr. FRIEDENWALD said that although some recent communications had reported high values for trypsin in achylia gastrica, he had, himself, found the values to be low in such cases. He felt that the low values were to be expected, because in achylia gastrica the stimulus to the pancreas by the acid chyme was lacking.

Dr. ALLEN ARTHUR JONES of Buffalo, N. Y., had found an irritable condition of the stomach in gallstone disease, with pyloric spasm and hyperchlorhydria.

Dr. KAUFMANN stated that when he was in doubt as to whether he was dealing with an ulcer or gallstones he made an examination of the stomach content; and if he found normal conditions, he considered that that favored the diagnosis of gallstones. He felt that a diminution of hydrochloric acid in ulcer cases showed the presence of a process leading to the healing of the ulcer. He considered the ferment test unreliable and had given it up, preferring the rennet test to it.

Dr. BROWN had found acidity always in gallstone disease, excepting when the latter was associated with appendicitis.

Direct Examination of the Duodenal Contents in the Diagnosis of Gall-Bladder and Pancreatic Affections.—Dr. MAX EINHORN of New York City stated that the macroscopical appearance of the bile was of great importance in diagnosis. If golden yellow and clear, it indicated a normal gall-bladder; if greenish yellow and turbid it portended a diseased state, frequently gallstones, while in catarrhal jaundice the bile often contained mucus. He said the duodenal contents containing bile and pancreatic secretion permitted a gauging of the pancreatic function.

Dr. HEMMETER said that in a great many analyses of duodenal condition he had never missed the diastatic ferment once; therefore, he had ceased to place any importance upon the rôle played by diastase in duodenal conditions.

Dr. WHITE asked whether the presence of a duodenal tube might not produce irritation and cause a secretion of mucus.

Dr. EINHORN remarked that he had found a number of cases in which amylopsin was absent. In reply to Dr. White he said he could merely give his own experience. In cases of catarrhal jaundice he sometimes had found no bile at first, but later bile and mucus had come through. Not only had he found mucus in catarrhal jaundice, but also in cases of catarrh of the duodenum; but the latter was unusual.

The Value of Colonic Inflation in the Diagnosis of Chronic Appendicitis.—Dr. EDWARD H. GOODMAN of Philadelphia said inflation of the colon was an equivocal means of diagnosing chronic appendicitis, but should not be employed in acute cases, as the risk of injuring the intestine was too great. He advised that inflation be regarded merely as an aid to diagnosis, history and physical examination being more valuable, and stated that the test was in no sense pathognomonic of chronic appendicitis.

Dr. LICHTY said that it was difficult to determine whether an appendix was diseased or not, even after removal, unless a microscopic examination were made. Therefore, he did not believe that the statistics on the subject were reliable.

Dr. HEMMETER asked whether Dr. Lichty meant that there might have been a diseased appendix, even though at operation he could find no evidence of appendicitis.

Dr. LICHTY replied that he meant that there was no evidence that could be distinguished macroscopically.

Dr. JACOB FUHS of Brooklyn, N. Y., had not found the test reliable, and asked Dr. Goodman whether he had used it in cases where adhesions were present.

Dr. GOODMAN stated that he had examined microscopically, all appendices that were removed, and several times, in cases where they were apparently normal, they were found to be the seat of chronic interstitial appendicitis. In seven or eight cases of adhesions, the tests were negative.

Abdominal Aneurysm as a Cause of Left-Sided Abdominal Pain.—Dr. EDWARD H. GOODMAN of Philadelphia said that the diagnosis of abdominal aneurysm might be a matter of great difficulty. In the cases in which the aneurysm sprang from the anterior wall of the aorta, he thought that the diagnosis was materially facilitated by the finding of a pulsating tumor; but that in dilatation of the posterior wall, the customary signs of aneurysm failed. In all cases with obscure left-sided abdominal pain (with, at times, hyperesthesia over the painful area) for which no adequate cause could be found, and which failed to exhibit physical signs of abdominal disease, aneurysm of the abdominal aorta should be considered as a cause. A fluoroscopic examination, with careful *x*-ray photographs, would be of valuable assistance in arriving at a correct diagnosis.

Dr. SMITHIES told of a patient who had a very large and hard abdominal tumor, which reached from the upper epigastrium to the public arch. There was no murmur, no thrill, and no evidence of elastic movement. The diagnosis made was cyst of the pancreas, probable dislocation of one of the solid organs, and abdominal aneurysm. An aneurysm four inches wide at the upper portion and three inches wide below was found at operation.

The Symptomatology of Gastric Cancer; An Analysis of 712 Consecutive Operatively and Pathologically Demonstrated Cases.—Dr. FRANK SMITHIES of Chicago said that in nine per cent. of all cases of gastric cancer there were no symptoms pointing to its existence. In such instances, exploratory operation or post-mortem examination gave the diagnosis. Gastric cancer might be expected at any age, he said. In the majority of instances there had been, he thought, some precancerous stage in which the disease might have been curable. He considered it impossible to say when a chronic ulcer might develop into cancer and when it would not.

Transition of Gastric Cancer into Ulcer and of Gastric Ulcer into Cancer.—Dr. JOHN C. HEMMETER of Baltimore considered it impossible to judge from a piece obtained at operation whether an existing cancer of the stomach had originated on the basis of a preexisting ulcer or not. The combination of ulcer and cancer in the same stomach had been seen. He thought that scars were not necessarily places of predilection for the formation of cancer.

Dr. FRIEDENWALD stated that according to his observation the maximum liability to cancer lay between the 40th and 60th year, the greatest proportion of cases occurring in males. He was convinced that only about 23 per cent. of the cases of gastric ulcer were transformed into malignant growths, and considered the figures of many writers too high. He felt that as the means of early diagnosis of cancer were very insufficient, exploratory incision should be urged upon all persons over 40 years having gastric symptoms which were not relieved with treatment.

Dr. JOHN DUDLEY DUNHAM of Columbus, Ohio, was in favor of operating on persons with epigastric tumor, as he thought that many might be saved years of life by means of a partial gastrectomy.

Dr. EINHORN felt convinced that a cancerous growth might develop on the base of a gastric ulcer, but considered these cases great exceptions. He thought that ulcers need not be treated surgically on account of the possibility of their producing cancers, as he did not consider the ulcer to be a precancerous stage.

Dr. JAMES TAFT PILCHER of Brooklyn, N. Y., stated that Dr. Mayo did not hold, as some seemed to think, that from 50 to 70 per cent. of ulcers developed into carcinoma, but that in the cases of carcinoma resected at the Mayo clinic evidence of preexisting ulceration was found in 50 to 70 per cent.

Dr. KAUFMANN did not think that all cases which the Mayos considered to be cancer were cancer. In his own experience he had found that the majority of cases of ulcer that he had followed out from fifteen to twenty-five years had not developed into cancer. They had either yielded to treatment or the patients had continued to suffer from them.

Dr. BLOODGOOD said that no physician should assume the responsibility of deciding whether an ulcer or lump that could be seen or felt externally was operable or inoperable, or whether it was cancerous or not. It was a pure surgical responsibility, he thought. In cancer of the uterus he felt that the responsibility rested with the gynecologist. In the case of cancer within the abdomen he considered the responsibility purely a medical one.

Dr. LICHTY said that on reviewing his cases of gastric ulcer he had found that there were very few that had become positively malignant. He thought if ulcer were the precancerous stage he should have found among his 500 cases, followed up for from fifteen to eighteen years, more cases of carcinoma.

Dr. SMITHIES stated that his series of cases was not at all comparable with any other series of cases, because he had taken 712 known instances of carcinoma and followed them up to find how many had arisen from gastric ulcer.

Dr. HEMMETER felt he could offer a ray of hope in regard to the diagnosis of cancer in the Abderhalden test.

Radiological Differential Diagnosis between Ulcer and Carcinoma of the Stomach.—Dr. A. F. HOLDING of New York City, after a review of the conflicting theories of the leading roentgenologists, expressed the belief that an ulcerative gastric lesion could not be recognized by any single irregularity of the bismuth shadow, but must be diagnosed by the interpretation of complex roentgenographic manifestations, and that an indurated ulcer could be distinguished from one which was undergoing carcinomatous degeneration only by means of the microscopic examination of a specimen. He stated that physicians and surgeons who had used the Roentgen method of diagnosing gastric lesions were its strongest advocates.

The Actual Demonstration of Duodenal Ulcer by the Roentgen Method.—Dr. A. W. GEORGE of Boston said that most investigators, in the past, had relied almost entirely upon the indirect method of examination, which method depended to a great extent upon so-called "symptom-complexes," *i.e.* hypermotility, exaggerated peristalsis, gastric stasis, and other functional disturbances, being derived chiefly from fluoroscopic study, whereas the direct method had for its foundation five definite propositions. If any of the five propositions could be disproved, then the direct school would not have the positive character that they now felt it was entitled to.

Diagnosis of Incomplete Forms of Pyloric Stenosis by Means of the X-Rays.—Drs. F. H. BAETJER and JULIUS FRIEDENWALD of Baltimore, Md., said in this paper that the *x*-ray was of great assistance in determining partial obstructions, particularly where the symptoms were not complete. Formerly it had been necessary to often wait a considerable length of time before the stenosis was sufficiently marked to warrant a positive diagnosis.

Dr. FRANKLIN W. WHITE of Boston asked whether the *x*-ray examinations of Dr. Holding were serial examinations or the more ordinary sort, and also whether he would feel it safe to rule out an exploratory operation by the results of *x*-ray examination alone. Dr. White did not consider the examination by means of the bismuth meal to give reliable information in regard to the motility of the stomach.

Dr. HEMMETER asked whether Drs. George and Holding believed in the theory of a pyloric reflex dependent on the chemical reaction in the duodenum.

Dr. S. J. MELTZER of New York City agreed with Dr.

White in regard to the effect of bismuth on motility.

Dr. KAUFMANN thought that the *x*-ray examiners were too much inclined to draw conclusions from their pictures without full consideration of all the other clinical factors. He felt that the use of the stomach tube gave them much better opportunities to determine whether there was intermittent pylorospasm than did *x*-ray examinations.

Dr. GEORGE C. JOHNSTON of Pittsburgh said in regard to the diagnosis of pyloric obstruction by means of the administration of a little bismuth mixed in water, that he considered it better to examine the behavior of the stomach when it contained what one was accustomed to put into it. The fact that a stomach refused to pass its contents through the pylorus might merely be an indication of a reluctance of the pylorus to open, which was not necessarily a surgical condition.

Dr. HOLDING said that in making reports of *x*-ray examinations he first stated what had been found and then gave his conclusions from the findings; if the one receiving the report desired to, he could ignore the latter. In answer to Dr. White Dr. Holding said that an exploratory operation was usually an evidence of inadequate *x*-ray examination. Regarding the different behavior of the stomach with bismuth and with food, Dr. Holding said that he had examined enough normal cases with bismuth in order to know what the normal stomach would do with the test meal. The speaker stated that he believed in the theory of a pyloric reflex dependent on the chemical reaction in the duodenum.

Dr. FRIEDENWALD said that their observations were made from many examinations, with the bismuth alone and with bismuth and food combined.

Experience with Boas Chlorophyl Test for Gastric Motility.—Dr. FRANKLIN W. WHITE of Boston, Mass., thought it was important to have a simple, exact test of the motor function of the stomach. He had found the Boas chlorophyl test, in forty cases, simpler and more rapid than other tests of gastric motility, also that appetite and reaction had little effect on it. While careful technique was necessary in aspirating the residue, yet he felt this was made easier by the watery solution used.

Dr. SEYMOUR BASCH of New York City said it was often impossible to know when one had all the water out by means of the colorometric portion of the chlorophyl test, but that the determination of the residue remedied that defect.

Dr. SMITHIES had found the giving of lycopodium spores in a glass of milk a useful comparative test with this general test.

Dr. KAUFMANN thought that no methodical examination for motility would give sufficient information in regard to disorders if those occurred at another time than when the examination was made. He considered the finding of acid in the fasting stomach in cases of gastrosuccorrhea as indicating a severe interference with gastric motility.

Dr. HENRY W. BETTMANN of Cincinnati, Ohio, was of the opinion that the only way to tell the actual muscular power of the stomach and its ability to empty itself was to test it under different conditions and form a composite picture. He considered the *x*-ray of great importance in supplementing one's knowledge regarding gastric motility by giving pictures of the duodenal and pyloric end of the stomach.

Dr. MELTZER asked whether the water used in this test could be absorbed from the stomach.

Dr. WHITE remarked that his test had been of one food only, and that all foods might not behave in the same way. He found that this test had missed no case of considerable motor disturbance. Experiments had proved that water was absorbed from the stomach.

Study of Methods of Lavage; the Treatment of Diabetics, Especially with Lavage.—Dr. JOHN B. SAWYER of Cleveland, Ohio, felt that the question of the efficiency of lavage was of especial interest because of the importance of the use of gastric lavage in diabetic patients. The thoroughness of the cleansing by his method, particularly of the upper portion of the stomach, which was usually missed with the patient in the upright position, had proved a factor in determining the success of the measure. He thought that less than obtainable efficiency in the procedure would probably account for less than satisfactory results from its use, and that stomach lavage by this method was certain to afford relief.

Dr. SMITHIES remarked that the hyperglycemia was not the real test to show why diabetic patients would improve or not under gastric lavage; most of them had benign obstruction of the pylorus, some intestinal intoxication and alterations in the gall bladder. Most of them also had hypercholesterinemia.

Dr. MELTZER said that the glycosuria in diabetics was not only a part of the disease, but also was an effort on the part of the body to get rid of the hyperglycemia and the intoxication of all the tissues that occurred through it.

Dr. AARON inquired concerning the dietetic treatment used in connection with the lavage.

Dr. LICHTY remarked that it would be interesting to know whether the patients treated in this way had increased in weight and in carbohydrate tolerance. He had noticed that patients with hyperchlorhydria seemed to have a peculiar feeling of well-being after an aspiration of the stomach.

Dr. WHITE thought that when a diabetic was treated with a careful diet and became sugar-free, his tolerance for sugar rising, the physician should be on his guard not to lay too much stress on some secondary treatment given at the same time, as the improvement was probably the effect of the skillful dietetic treatment.

Dr. SAWYER said that all diabetics needed to be protected against constipation and similar disturbances. He stated that the carbohydrate tolerance was increased by this treatment and patients treated with lavage could take a larger quantity of starch than patients not so treated. He believed that there was a stimulus exercised by the lavage on the mucous membrane, which changed the chemical activity of the cells. Patients also increased in weight.

Some Clinical Aspects of Gastric Hemorrhage.—Dr. J. A. LICHTY of Pittsburgh stated that unless the acute ulceration were recognized and differentiated from the end results of the ulcer the results would not be very good. He referred to a number of his patients who had had frank hemorrhage from the stomach or bowel, or both, soon after rectal feeding was instituted for the treatment of supposed gastric or duodenal ulcer. He thought that in acute peptic ulcer or acute exacerbation of chronic ulcer, when accompanied by hyperchlorhydria, food should not be withheld from the stomach at once, but that when a hemorrhage occurred food should be withheld until the hemorrhage was controlled. He considered surgical treatment for gastric hemorrhage to have a very limited but definite field, namely, in chronic ulcer. Hemorrhage in acute gastric ulcer should not be treated by operation.

Postoperative Gastric Hemorrhage and Posterior Gastroenterostomy with a Long-Loop Roux Method, Modified.—Dr. J. C. BLOODGOOD of Baltimore had never been able to get enough cases on which to base any conclusion as to the best treatment in cases of hemorrhages from the stomach that threatened life. In deciding which of several methods to choose in order to restore the continuity between the stomach and the intestines the speaker said that the decision might be based on the immediate mortality, the post-operative complications, or the ultimate result. He stated that the ultimate of almost any type of operation upon the stomach would be successful if the case had passed the dangerous rocks of immediate mortality and post-operative complications. As far as he could see the difference in mortality from the various operations in the hands of experienced surgeons was infinitesimal. In Dr. Bloodgood's opinion the two most dangerous post-operative complications were duodenal dilatation and hemorrhage; the former could be avoided by being careful not to close the duodenum. He advised the avoidance of the long loop operation, if possible, owing to the danger of producing peptic ulcer and hemorrhage.

Dr. WILLY MEYER of New York City considered the Einhorn string method of testing for duodenal ulcer most valuable. He advised the using of injections of human blood serum or direct transfusion in cases of profuse hemorrhage. He had also found useful in stomach hemorrhage the injection of bismuth and water into the stomach.

Dr. FRED T. MURPHY of St. Louis felt sure that all cases of vicious circle came back to poor technique, being the fault of the operator and not of the operation. He also thought that with good technique peptic ulcer might be looked upon as a surgical curiosity and need not be considered as a serious risk in cases of stomach operation.

Dr. EINHORN said that when the string test showed a definite stain the surgeon should not ignore such indications. He depended largely on the appearance of the stain for his diagnosis: a localized stain indicating

an ulcer and a spread-out stain being usually due to an inflamed condition of the mucosa, which might be caused by the thread's being pulled up and down. He said there was not a week passed that he did not have patients come to his clinic, having been operated on from six months to a year and a half previously, with definite and severe symptoms in the stomach.

Dr. MELTZER asked Dr. Bloodgood whether he had ever come across an instance in which the hemorrhage had been stopped after a laparotomy had been done and nothing else and the wound closed again.

Dr. HEMMETER said that a peptic ulcer might be produced by a poison called sepsin, from fermenting yeast. Vagotonus also favored the formation of peptic ulcer by producing spasm of the pylorus; therefore it was impossible for the surgeon to remove the cause of gastric ulcer.

Dr. SMITHIES stated that out of 163 cases shown to be ulcer in only seven was the string test of any service.

Dr. JOHNSTON had had a large experience with the Einhorn thread and said that in not a single instance in which the diagnosis of gastric or duodenal ulcer had been made by this means, and operation advised had they failed to find the ulcer in the exact place in which the thread indicated. He thought their aim should be to prevent a return of the mechanical conditions that existed before operation and which had served to produce the ulcer.

Dr. LICHTY claimed that in his case they had used every means to stop the hemorrhage referred to by Dr. Willy Myer as well as many others, but nothing had any effect but a surgical operation. He said he hesitated to turn a patient over to a surgeon when he felt that the pylorus was still reasonably patulous. To him the value of the string test had increased in the last few years because of his being able to interpret it more accurately, its value being confined to open ulcer.

Dr. BLOODGOOD said that if the pylorus were closed and an anastomosis done there would be the risk of duodenal dilatation, which was always fatal. He never did a posterior gastroenterostomy if he could do anything else.

A Further Report on Resection of the Esophagus for Carcinoma.—Dr. WILLY MEYER of New York City gave the history of a series of cases illustrating the progress that had been made in operative surgery, which progress lay in the following two points, the necessity of which he felt had been thoroughly recognized: (1) Removal of the proximal stump of the esophagus from the posterior mediastinum and transposition of the same under the skin of the thorax, and (2) free drainage of the pleural cavity immediately following operation in each and every case.

Intestinal Obstruction.—Dr. FRED T. MURPHY of St. Louis said that the recent experimental work on intestinal obstruction emphasized in the treatment of these cases the need of early operation, the value of local anesthesia, the necessity of relief from dehydration and loss of heat, the avoidance of any trauma that might tend to destroy the mucosa and tend to the absorption of toxins, and the need of removing segments of intestine in which the mucous membrane was so damaged as to permit of the absorption of the toxic gut content. The loss of the normal protective power of the mucosa he considered of greater importance in the production of symptoms than the presence of the toxin in the intestine.

The Diffusion of Bacteria into the Intestinal Wall.—Dr. FENTON B. TURCK of New York City referred especially to the penetration of both motile and nonmotile forms between the cells of the submucosa where they underwent rapid bacteriolysis. He also made some reference to certain new staining methods for the determination of aminoacid reaction of the autolytic products found in that submucous region or, as he preferred to call it, "zona transformans."

Dr. LICHTY asked Dr. Turck whether these experiments went as far as the walls of the stomach or only took in the intestine.

Dr. TURCK replied that they would also pass through the stomach wall.

Officers.—The following officers were elected for the ensuing year: *President*, Dr. J. C. Bloodgood of Baltimore; *First Vice-President*, Dr. Charles G. Stockton of Buffalo; *Second Vice-President*, Dr. William Gerry Morgan of Washington, D. C.; *Secretary and Treasurer*, Dr. Franklin W. White of Boston.

Miscellany.

Overhauling the Automobile.—H. Massac Buist states that motor cars are curious things, in that as far as matters of habit go they seem to be alive. Thus a car may work quite reliably day after day for weeks at a spell, doing a given series of rounds, calling a halt every mile or two, as does the average doctor in the exercise of his profession. But if the same car be asked to go fifty or seventy miles without a halt it is ten to one that some minor part of the mechanism fails in the most annoying manner, leading to a breakdown involving a loss of hours. Reparatory to a lengthy run the machine will want looking over in a more special fashion than is done ordinarily in connection with its daily work in the doctor's service. Under these conditions it does not go long enough at a spell to run any serious risk of damage even should there be insufficient oil in the back axle or gearbox, or lack of grease in the universal joints. In most such cases ample warning would be given by way of gradually increasing squeaking. Before starting out, however, all those points should be specially checked. It is besides as well to unscrew the valve caps and have a look at the condition of the engine's interior in regard to carbon deposit. Assuming, therefore, that the motor is clean and that it will be given a reasonable chance of keeping clean by drawing off the oil from the crankcase; that it has been replenished with new and clean supplies and is not suffering from loss of compression; and that all water connections and all other parts where leaks might occur have been looked over; a start may be made with a fair certainty of having no motor trouble. In regard to the chassis in general, apart from such ordinary attention as the filling of grease cups at regular intervals, one should pay particular heed to the universal joints in connection with the propeller shaft. It is particularly essential that the grease put into the joints at either end of the propeller shaft is adequately secured in the covering to those connections. If these parts are run dry, sooner or later a broken propeller shaft joint will be sustained, than which there is scarcely any form of motor accident more dangerous. If the fore end goes it drops like a pole, which the back axle has to jump. Brakes should be gone over, particularly with a view to ensuring that they are acting in an absolutely compensating fashion, the pull being equal on either back wheel. It is as well to take up any slackness of the steering and particularly to supply all steering joints with lubricant. Next, as the car stands in the garage the wheels should be checked for alignment. If a wheel be ever so little out of true tires wear in extraordinarily quick time. Runs longer than those usual in the execution of the doctor's daily work demand, also, attention to the tires. The medical man will save money by taking off all tires showing any appreciable wear, and replacing them with new shoes before starting out on a run the length of which cannot be foreseen. The old shoes can be brought into use again afterward and worn to the ordinary limits. Attention to all of the above details is necessary from time to time even if no unusually long tour is contemplated. This attention is demanded as a measure of safety as well as of economy.—*British Medical Journal.*

CHRONIC INTESTINAL STASIS.*

BY ALFRED C. JORDAN, M.D., CAMB., M.R.C.P.

LONDON.

I HAVE the honor to address you on one of the most fascinating and far-reaching branches of medical study; a vast realm that has been opened up by the genius and insight of our great surgeon, Sir Arbuthnot Lane.

Intestinal stasis is a chronic disease due to the absorption of poisonous substances from the alimentary canal. The disease itself may be so insidious as to escape notice, while a complication may produce severe and urgent symptoms, and compel instant attention. In this way we have hitherto lost sight of the fundamental disease—the stasis—and we have fixed our attention on the complication, regarding this as a primary disease.

The general signs and symptoms of intestinal stasis are too well known to require a detailed description. A full and most graphic account is contained in Sir Arbuthnot Lane's recent paper (*Practitioner*, March, 1914).

I am concerned with the radiological demonstration of the changes found in cases of intestinal stasis. When first I took up this work I was handicapped by the belief that the patient must be "prepared" for the bismuth meal by giving him purges and enemata, and that he must take his bismuth

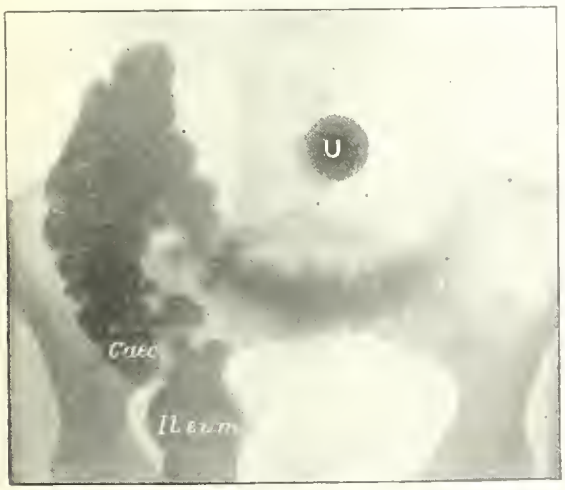

FIG. 1.—Simple ileal stasis, taken on the couch 37 hours after a bismuth meal in a woman aged 40 suffering from advanced cystic disease of the breasts.

in the form of a "meal" while fasting. Many radiologists adhere to this mode of preparation still, but I am perfectly sure that once they have made up their minds to abandon it they will never return to it.

The best way to give the bismuth is in the form of an emulsion to be taken about an hour after an ordinary breakfast. The reasons for this were given

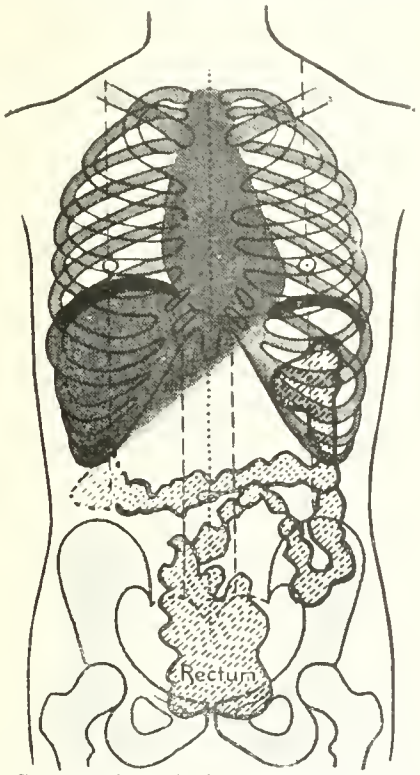

FIG. 2.—Great stasis in the large intestine, with elongation of the pelvic colon, taken on the couch 80 hours after a bismuth meal in a woman aged 46 suffering from advanced cystic disease of the breasts. There was also extreme ileal stasis, and the patient showed all the usual signs and symptoms of chronic intestinal stasis.

fully by me in a recent paper (*Brit. Med. Jour.*, November 22, 1913). In the vertical posture the emulsion is seen to pass through the esophagus rapidly, and to fall at once to the great curvature of the stomach. The patient then lies on the couch on his right side to allow the bismuth to fill the pylorus and duodenum. After a minute or so he lies on his back, and is examined with the fluorescent screen. In the normal case the duodenum is small and short, its vertical portion measuring $2^{3}/_{4}$-$3^{1}/_{4}$ inches; in a few seconds a duodenal peristaltic wave starts near the top of the duodenum, and carries before it the whole contents of the duodenum without delay through its four parts and on to the jejunum. At the end of three or four hours there is no longer any bismuth in the stomach or duodenum; the whole of it is in the lower abdomen, partly in the lower coils of the ileum, partly in the cecum and ascending colon. In perfectly normal cases the lower ileal coils lie above the pelvic brim,

*Lecture delivered at the New York Polyclinic Medical School and Hospital, April 14, 1914.

and there is never a very large collection of bismuth in these coils, the passage through the ileocecal valve being free. One of the very earliest effects of stasis is to cause the lower ileal coils to drop into the pelvis. There is then a long rise from the

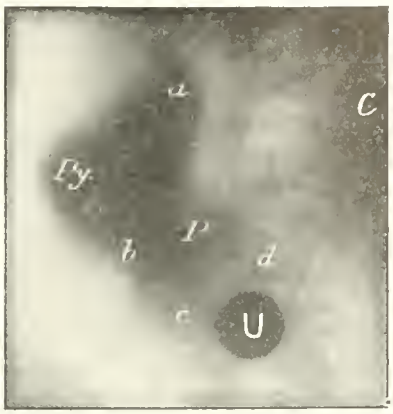

Fig. 3.—Taken on the couch after a bismuth meal in a woman aged 47, showing the duodenum and the pyloric portion of the stomach. The woman suffered from severe glycosuria; at the age of 30 she had exophthalmic goiter for six months. The screen showed active gastric peristalsis with pyloric spasm. The duodenum was dilated, and showed strong "writhing" peristalsis with repeated return of the bismuth from the third to the second part of the duodenum, only traces of bismuth having entered the jejunum at the end of 15 minutes. C, P, cardiac and pyloric portions of the stomach; Py., pylorus a, b, c, d, the four parts of the duodenum; U, the umbilicus. (See also Figs. 4, 5, and 6.)

pelvis to the cecum. Spasm of the ileocecal valve occurs, and adds to the difficulty. The last inches of the ileum become hypertrophied to a thick cord which is easily felt. In many cases the weight of the overloaded cecum and ileum causes a constant pull on the mesentery of the ileum whenever the patient is upright; a thickening then appears in the mesentery at the point where the pull is greatest. The point of greatest strain varies from case to

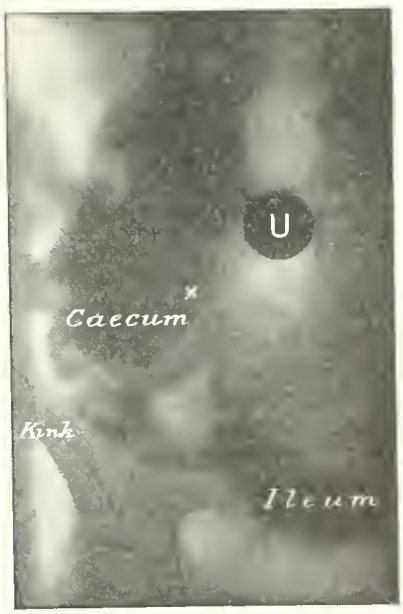

Fig. 4.—Taken on the couch 9 hours after the same bismuth meal. There was still a large amount of bismuth in the stomach—kept back by the pyloric spasm. The terminal coil of the ileum was tortuous and thick-walled; it was firmly fixed in the right iliac fossa (Lane's kink). The appendix, seen beneath the cecum, was freely movable, and appeared healthy.

case; often it is within an inch of the ileocecal valve (Fig. 14); sometimes it is in the right iliac fossa about four inches from the valve (Figs. 4, 5, and 19); in other cases again it is just above, or just below the pelvic brim.

It is clear, then, that the ileal kink is not the primary cause of the ileal stasis, although the kink, when present, aggravates the stasis, at any rate in the upright posture. I find there is still much misunderstanding on this point. It is the ileal stasis

Fig. 5.—Taken 22 hours after the same bismuth meal, showing the ileal kink as before with extreme ileal stasis, the lower ileal coils being still well filled with bismuth.

which produces the kink, by pulling on the mesentery of the ileum. Some of the worst cases of ileal stagnation occur in feeble women, and in them a kink may never appear (Fig. 1). In such cases there is often extreme dropping of the large intestine, the cecum occupying the deepest part of the pelvis. The ileal contents have not then to negotiate a rise to the cecum; the difficulty must be enhanced by the ileocecal valve, which gets into a state of spasm seldom fully relaxed.

With regard to the large intestine I propose to say little, except incidentally to explain its effect on other parts. In normal cases the bismuth begins to enter the cecum in three to four hours; in six to eight hours it has reached the middle of the transverse colon; in eight to ten hours the splenic flexure, and in eighteen to twenty-four hours the rectum. At this stage (twenty-four hours) there is usually bismuth in all parts of the large intestine, fairly evenly distributed. At the end of forty-eight hours

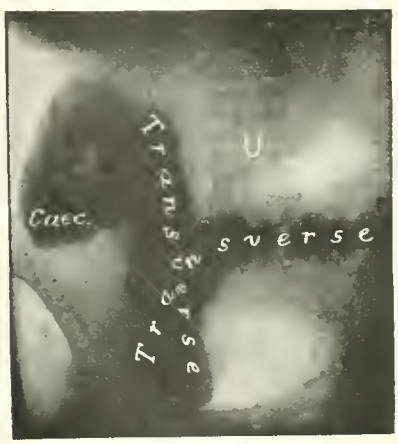

Fig. 6.—Taken on the couch 47 hours after the same bismuth meal; i.e. at a time when all the bismuth would have been evacuated in a normal case; the transverse colon dips vertically into the deepest part of the pelvis, and no bismuth has advanced beyond the middle of the transverse colon. After 95 hours no bismuth had been passed, and very little had got beyond the transverse colon. A few days later diabetic coma supervened, and the patient died.

all the bismuth should have been evacuated. The delay in the large intestine in stasis is often extreme, and after one hundred hours there may be little bismuth beyond the splenic flexure. Undoubtedly a good deal of toxic absorption occurs

from the stagnant contents of the large intestine, but the greatest harm arises from the damming back of the contents of the ileum, these ileal coils becoming infected with microbes from the cecum. The ileum is sterile in health, and is not equipped by

Fig. 7.—Atheromatous elongation and dilatation of the aortic arch, in a "stasis" subject. The dotted line is in the long axis of the heart, more oblique than normal in consequence of the aortic elongation. No tissue escapes the deleterious action of the intestinal toxins.

Nature to deal with microbic invasion, while the large intestine can cope with a considerable amount of bacteria.

The absorption of poisons into the circulation enables these poisons to gain access to every organ and tissue of the body, and no tissue escapes their baneful influence. Thus we get many of the general symptoms of stasis; the headache and depression, the aching muscles and joints, the unhealthy skin, etc. The glands suffer early, one of the first changes due to stasis being in the breasts, which become nodular. The condition of the breasts is a very good index for gauging the progress of a "stasis" patient while under treatment.

Fig. 8.—Stomach and duodenum, taken on the couch after a bismuth meal in a man aged 47, suffering from mucous colitis and a rheumatoid left hip. Both had persisted for a year. There had been no symptoms referable to the stomach or duodenum. The first part of the duodenum is much dilated and tensely filled, ending below in a blunt point beyond which no bismuth was seen to pass. The obstruction was due to spasm set up by a duodenal ulcer (in the position of the arrows). C, P, cardiac and pyloric portions of the stomach; Py., pylorus; a, the first part of the duodenum; U, the umbilicus (see also Figs. 9-12).

In neglected cases chronic cystic disease appears in the breasts, and finally they become cancerous (Figs. 1 and 2). Other glands suffer, and the pancreas is found to be hard and nodular in operations for stasis. Cancer of the head of the pancreas may be the last stage in the history. The suprarenal glands probably suffer a similar change, and many cases of glycosuria result from changes in the pancreas and the suprarenals (Figs. 3-6). The pigmentation of the skin of stasis subjects is probably due to supra-

Fig. 9.—Showing the pyloric end of the stomach and the dilated first part of the duodenum in the subject of Fig. 8.

renal changes. Other ductless glands are affected; the thyroid gland atrophies, or else undergoes changes leading to exophthalmic goiter. The surest proof that these diseases are due to stasis is the fact that they clear up—permanently—on the cure of the stasis, whether by operation or by treatment. Atheromatous elongation, and later dilatation of the aortic arch occurs at an early age in the subjects of intestinal stasis; this change is easily recognized by radiology, and is capable of accurate measurement (Figs. 7 and 15). The walls of the aorta evidently share the deterioration of all the tissues. It is interesting to speculate how far changes in the pituitary gland, leading to raised blood pressure, act as the exciting cause of the dilatation of the aorta.

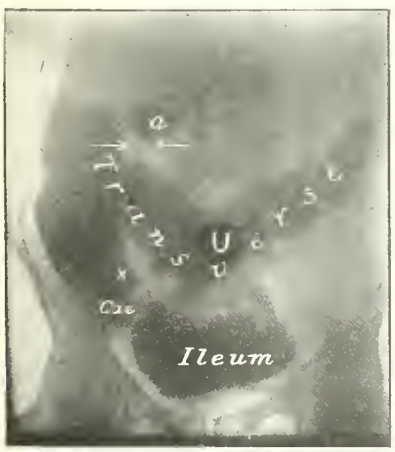

Fig. 10.—Taken on the couch 6 hours after the same bismuth meal, showing ileal stasis. There was still a little bismuth in the stomach, and the dilated first part of the duodenum (a) was again shown well filled with bismuth entrapped above the ulcer (arrows). U, umbilicus; the X marks the ileocecal entrance.

Rheumatoid arthritis is a frequent result of stasis, and is relieved permanently on the abolition of the stasis (Figs. 8 and 24).

The microbes which have entered the stagnant ileum from the cecum ascend to the upper reaches

of the small intestine. Thus the duodenum becomes infected, and the ducts which open into it cannot escape infection. In this way we get the gall-bladder infected; it becomes distended, and gall-stones are formed in it.

FIG. 11.—Taken 9½ hours after the same bismuth meal, showing the same conditions as Fig. 10 (*q.v.*). The appendix appeared healthy.

This brings us to another aspect of stasis—one of the most important of all, and the one which is still most open to doubt by the medical public, although the facts are so clear that there is no room for doubt. I refer to the effects of intestinal stasis upon the duodenum and the stomach. In studying this part of the subject radiology is able to give the greatest assistance, and the changes revealed by a

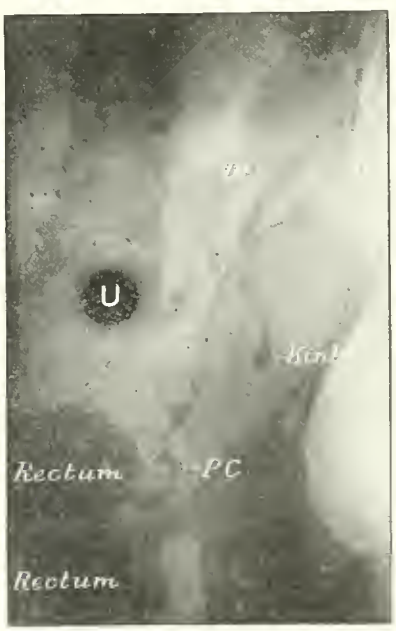

FIG. 12.—Taken 26 hours after the same bismuth meal, showing evidence of mucous colitis, the latter portions of the transverse colon, and the whole of the descending and iliac colon being in a state of tonic contraction, and holding only an irregular thin line of bismuth, mixed with mucus. The iliac colon is firmly fixed in the left iliac fossa at one point, constituting a well-marked "last kink" (Lane).

bismuth meal are most striking and characteristic. I have already described the appearance and behavior of the normal duodenum. In stasis the state of affairs is quite different: the duodenum is much too large; its vertical part measures 4, 5, or even 6 inches in length instead of $2^{3}/_{4}$-$3^{1}/_{4}$ inches, as in healthy subjects. These measurements are taken orthodiagraphically, so they are strictly comparable. The duodenum is also much wider than normal; often it is double the normal width. Its first part in

FIG. 13.—Typical chronic ulcer of the lesser curvature in a woman, aged 58, taken on the couch after a bismuth meal, showing the depressed base of the ulcer, and the tight spasmodic constriction of the circular fibers of the stomach over the ulcer. As usual there was persistent spasm at the pylorus, with dilatation and dropping of the pyloric portion of the stomach. The duodenum was elongated and dilated, especially its first part; it showed marked "writhing" contractions, with repeated regurgitation, only small amounts entering the jejunum in spite of the strong duodenal peristalsis. After 24 hours hours fully one-third of the bismuth was still in the pyloric portion of the stomach. C, P, cardiac and pyloric portions of the stomach; U, umbilicus; Py., pylorus; a,b,c, first, second and third parts of the duodenum. The arrows indicate the persistent pyloric spasm, resembling organic stenosis (see also Fig. 14).

particular is often greatly dilated. The increased size of the duodenum is not the only change, though it is a sufficiently striking one. Far more remarkable is its altered behavior. It fills well with bismuth (provided the conditions be arranged suitably), but it does not empty itself into the jejunum with a single peristaltic wave as in normal cases; the "static" duodenum shows excessively powerful peri-

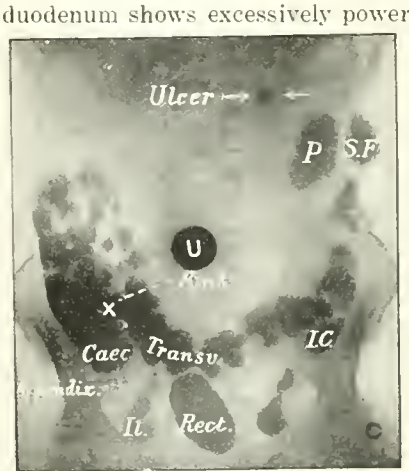

FIG. 14.—Taken on the couch 47 hours after the same bismuth meal, showing bismuth still present in the pyloric portion of the stomach and in the depressed base of the ulcer. There was an ileal kink; the appendix was normal. There was great stasis in the large intestine, and at the end of 72 hours most of the bismuth was still in the cecum, the ascending colon and the dropped transverse colon. (Confirmed by operation by Sir Arbuthnot Lane, and all the symptoms—both general and those due to the gastric ulcer—relieved by "short-circuiting" the ileum into the rectum. The stomach was not touched. Six months later she was at work, feeling quite well.) P, pyloric portion of stomach; Il., ileum; S. F., splenic flexure; I. C., iliac colon. The X marks the ileocecal entrance.

stalsis, wave after wave passing along its four parts; one has only to look at it to realize that it is working against an obstruction; the bismuth is driven down to the lowest part of the duodenum, and often well on into the fourth part, only to re-

turn again, time after time, to the vertical part as each wave passes over. The whole duodenum alters in form continually during the occurrence of this phenomenon, giving the appearance of "writhing." In severe cases this "writhing" peristalsis continues

FIG. 15.—Taken on the couch after a bismuth meal in a woman aged 60, showing a carcinoma of the stomach. The *x*-ray appearances are those of chronic ulcer in caricature. The wire marks the outline of a tumor which was felt. The duodenum was dilated, and showed well-marked "writhing" contractions. The aortic arch showed considerable atheromatous elongation, and slight fusiform dilatation. C, P, cardiac and pyloric portions of the stomach. Py., pylorus. a, b, c, first, second and third parts of the duodenum; U, umbilicus. Undoubtedly the tumor originated in a chronic ulcer of the lesser curvature, though the deviation from the typical form is considerable, the tumor being a large one.

hour after hour, a single spurt of bismuth finding its way through to the jejunum every ten minutes or so. The duodenum seems never to tire. Of course it should be understood that all stages occur between the normal duodenum and the extremely dilated, writhing duodenum of severe stasis.

What proof have we that the static duodenum is due to the downward pull on the commencement of the jejunum caused by overloading of the lower ileal coils? The proof is manifold and complete. In the first place the downward pull on the jejunum can be observed at operation. The top of the jejunum,

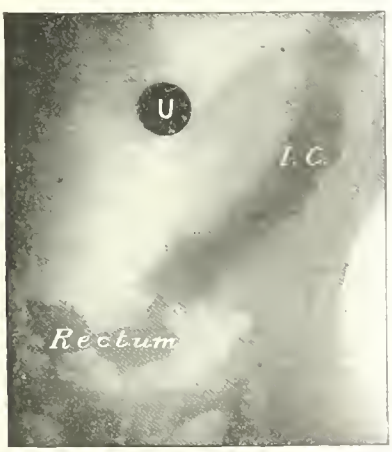

FIG. 16.—Cancer of the pelvic colon, taken on the couch 96 hours after a bismuth meal in a man aged 56. I. C., iliac colon; the arrows show the seat of obstruction in the pelvic colon.

moreover, is found empty, and often it is the subject of torsion, the effect of the duodenojejunal kink being increased greatly by this torsion. The radiologist, while examining the duodenum, can actually see the bismuth forced into the fourth part of the duodenum, almost up to the junction with the jejunum; eventually some bismuth is forced through, and then the radiologist can see that the jejunum passes down vertically at its commencement. A few hours later he is able to con-

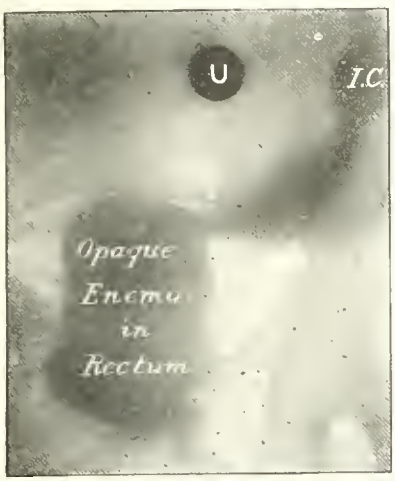

FIG. 17.—Taken after Fig. 16, the rectum having been filled with barium fluid, to show the obstruction in the pelvic colon.

vince himself that there is stasis in the lower coils of the ileum. Few things in medicine are more constant; if we find a distended duodenum we are certain to find ileal stasis, and conversely, if we find a normal duodenum, with free duodenojejunal junction we are most unlikely to find any material amount of stasis in the lower ileum. The proof is more perfect even than this: there is a definite quantitative relation between the amount of ileal stasis and the amount of duodenal distention; thus a high degree of duodenal distention will be found associated with great ileal stasis, while slight duodenal distention goes with slight ileal stasis. Of course the proportion is not mathematically accurate, but it is nearly enough so to furnish clinching proof of the dependence of duodenal distention on ileal stasis.

The distended duodenum causes no subjective symptoms, but if it is congested the patient be-

FIG. 18.—"Diverticulitis" of the pelvic colon in a man aged 54. Severe symptoms, including albuminuria and a high blood pressure, were relieved by the operation of "short-circuiting" carried out by Sir Arbuthnot Lane.

comes aware of its presence at once; he feels pain in this region, and there is tenderness to pressure over it; the tenderness is often attributed to the gall-bladder. If the duodenum has become infected with microbes from the stagnant ileum we shall

probably get ulceration in the duodenum (Figs. 8-12). No normal duodenum gets ulcerated; a chronic duodenal ulcer occurs only in the distended duodenum of chronic intestinal stasis. It follows that one cannot have a duodenal ulcer without ileal

Fig. 19.—Ileal kink in a man aged 57, taken on the couch 10½ hours after a bismuth meal. (See also next Fig.)

stasis, and this accords entirely with my experience.

The distended duodenum has a very definite effect on the pylorus, which closes tight to prevent reflux from the overfull duodenum. The pylorus gets into a state of permanent spasm (Fig. 13), its contents become too acid, and this leads to a further increase of the spasm, for physiological experiments have proved that no acid can enter the duodenum without setting up an immediate tight closure of the pylorus. There is delay in the emptying of the stomach, and this organ is overloaded and dilates. The great curvature drops, and the transverse colon, also heavy with the weight of its stagnating contents, drops with it. Thus we get an abnormally great strain on the lesser curvature, and especially on the two "ligaments" of the stomach—the pylorus and the esophagus. A chronic ulcer is apt to appear at the pylorus, this part being accessible to the microbes which infect the "static" duodenum, or, if the pylorus drops, the point of greatest strain is shifted toward the esophagus, and the ulcer appears at some point along the lesser curvature (Figs. 13 and 14).

Fig. 20.—Taken 47 hours after the same bismuth meal, showing obstruction by bands just beyond the hepatic flexure. (Confirmed by operation.)

With the appearance of an ulcer in the stomach the acidity of the gastric contents increases still more, and the pyloric spasm becomes so severe and constant as to simulate organic stenosis (Figs. 13 and 14), and the radiologist must be very wary in the manner of carrying out his investigations to avoid this pitfall.

Fig. 21.—Cancer of the ascending colon in a man aged 57. There was a movable tumor in the position marked by a wire. A thin streak of bismuth ran along the outer side of the ascending colon, the tumor being attached to the inner wall. The appendix (normal) is shown well filled with bismuth.

The *x*-ray appearances of chronic ulcer of the lesser curvature are quite characteristic, especially on the couch. The depressed base of the ulcer fills with bismuth; the raised margins of the ulcer are shown, and there is a tight hour-glass constriction of the stomach over the region occupied by the ulcer, so that the stomach appears divided into two parts, separated by a narrow isthmus (Fig. 13). An important point to remember is that this hour-glass constriction is permanent except during general anesthesia. The radiologist must bear this in mind, lest he diagnose a cicatricial contraction, and the surgeon must not forget it, for when operating under general anesthesia he does not see a constriction, and he may not realize that the stomach will be drawn in again at the seat of the ulcer as soon

Fig. 22.—Taken 11 hours after a bismuth meal in a woman aged 35, short-circuited a year previously by Sir Arbuthnot Lane. Showing the termination of the ileum, and the rectum full of bismuth. Some bismuth had run up to the splenic flexure; the following morning this had come down again. Il., ileum; I. C., iliac colon; the X marks the union between the ileum and the rectum.

as the patient has recovered from the anesthetic. I have seen a surgeon make his gastrojejunostomy opening at the level of a chronic ulcer of the lesser curvature and the result was promptly fatal.

If we were to make an artificial hour-glass con-

FIG. 23.—Taken 5 hours after a bismuth meal in a woman aged 26, nine months after colectomy. All the bismuth is in the rectum except traces in the last four inches of the ileum. The duodenal distension and the pyloric spasm had been relieved almost completely.

striction in a healthy stomach we should expect the pyloric portion of that stomach, beyond the constriction, to become small (for it would never be properly filled), just as the entire stomach becomes small in cases of stricture of the esophagus. The fact is exactly the opposite in chronic ulcer of the lesser curvature; the pyloric portion of the stomach is always large and dropped (Fig. 13); in the most extreme cicatrical hour-glass stenosis of the stomach the great curvature may be in the pelvis in the upright posture. This affords the most striking confirmation of the fact that the chronic ulcer of the lesser curvature occurs, not in a healthy stomach, but in the enlarged stomach produced by constant pyloric spasm.

The symptoms caused by these chronic gastric ulcers are often vague and difficult to interpret clinically, and they are not often diagnosed correctly except by the *x*-ray method, when the diagnosis can be made with certainty as a rule. One of the dangers of leaving these ulcers untreated is due to their tendency to become malignant after a time, and I have a number of instances of carcinoma of the stomach exemplifying various stages in the transition from a typical chronic ulcer to an extensive malignant growth. The *x*-ray appearances are those typical of a chronic ulcer, but with more or less deviation from the typical picture due to the malignant involvement (Fig. 15).

Thus intestinal stasis is shown to be an important cause of cancer, not only in the stomach, but also in the pancreas, the liver and bile-ducts, and in the breasts. Cancers occur also in the large intestine as the result of stasis; this is readily shown. In the rectum (Figs. 16 and 17) and in the cecum (Fig. 21) the long-continued irritation of stagnant feces is responsible for the growth; in the hepatic flexure region and in the first part of the transverse colon immediately beyond the hepatic flexure fecal accumulation is often due to bands continued down from the lower surface of the liver over the pylorus and gall-bladder (Fig. 20). These bands are found in a fair proportion of stasis subjects. The iliac colon, again, is often tied to the left iliac fossa by bands, these being the first to form in the body. These bands sometimes cause obstruction and lead to a condition of chronic congestion with yielding of the bowel-wall between the bands and the production of the disorder known as "diverticulitis" (Fig. 18). Following upon this long-continued obstruction we may get the appearance of a cancer in this region.

Needless to say the bearing of all this new knowledge on treatment is of the greatest importance.

I propose to say but little concerning treatment, and only in its relation to radiology. Having ascertained the existence of stasis in a particular case, and the presence of one or more of its complications, the question will always arise—should we go to the root of the matter and deal with the stasis, or should we apply our treatment to the complication,—the end result of the stasis—*e.g.* a gastric or duodenal ulcer. The answer is simple:—leave the end result alone if you can, *i.e.* if it is not causing stenosis, or becoming malignant, or impacted in the case of gallstones. If you treat the end result (*e.g.* by performing a posterior gastrojejunostomy for ulcer) you will give your patient temporary relief which may be great, but you will not cure his stasis. Or again, if you merely remove his appendix, which has become (secondarily) congested or kinked, no lasting benefit will result. In proof of this I would mention the very large number of patients sent to me for investigation by the *x*-rays at some period after one of these operations had been performed. They are sent to me because they are not cured; they are suffering from the general symptoms and signs of stasis; or perhaps some other complication has arisen, *e.g.* colitis.

The rational treatment of stasis is directed to the abolition of the undue retention of the contents of the lower ileum and the large intestine. In slight cases this may be done by the administration of liquid paraffin to accelerate the progress of the feces through the large intestine, and by

FIG. 24.—Rheumatoid arthritis, a disease frequently seen in the subjects of chronic intestinal stasis. The cancellous tissue of the bones is rarefied. The joint trouble subsides permanently on the relief of the stasis.

a spring support for the lower abdomen, to prevent the dropping of the large intestine and the lower coils of the ileum, and to obviate the evil consequences of an ileal kink if there be one.

In severe cases of stasis, too advanced to gain

sufficient relief from the above treatment, operative measures are needed; short-circuiting the ileum, near its lower end, into the rectum, and making a kink in the iliac colon above the short-circuit to prevent or diminish the regurgitation of the ileal contents from the rectum into the descending colon. Often there is already a well-developed kink in this region (Fig. 12), or there is a slight kink which can be made more effective at the operation. In some cases, where the large intestine is very unhealthy, and would cause flatulent distension and other trouble if left, Sir Arbuthnot Lane now removes the whole big bowel above the short-circuit opening at the time of the first operation. Formerly he would do this at a subsequent operation if it proved necessary; with increased experience, however, one is now able to judge, in a particular case, whether the big bowel must be removed, or may be retained. All the details of the operations have been described by Lane, and are now well known and are practised extensively by a number of prominent surgeons throughout the world.

We come now to the results of the radical treatment of stasis from the radiological standpoint: Can we show, by radiology, that the stasis has been relieved? Certainly we can; in a successful case the whole bismuth meal is in the rectum after 6 or 8 hours (Fig. 23). The stasis has been cured. If the large intestine has been left there may be some bismuth in the descending colon for a few hours (Fig. 22), but as soon as the patient has an evacuation this comes down and is passed with the rest. Some of the cases in which the bismuth passes back, not merely into the descending colon but right back to the cecum, are those in which the subsequent removal of the big bowel becomes necessary on account of flatulent distension and tenderness due to the irritation set up in the bowel wall by the retention of lumps of secretion in the big bowel.

The question will be asked, what is the effect of the radical cure of stasis upon the distended duodenum? If the explanation ascribing the "static" duodenum to the downward pull on the upper jejunum be the true one, then the cure of the ileal stasis should abolish this downward pull, and should, therefore, relieve the duodenal distention. Does it do so? Yes. I have reinvestigated a large number of patients after short-circuiting, at varying intervals, from three weeks to several years, and the general conclusions are as follows: The duodenal obstruction, as shown by "writhing" contractions, and repeated return of the bismuth toward the pylorus, are relieved at once by the 3 or 4 weeks recumbency following the operation, and do not come again even after the patient has resumed ordinary conditions of life and work. The duodenum does not return at once to its normal size, but gradually—in the course of months—it becomes smaller and shorter, though in old, neglected cases the duodenum tends to remain permanently more "baggy" than normal; but the chief point is that the duodenum never again becomes distended; it is no longer found full of bismuth; its outlines can be sketched only by observing small quantities of bismuth as they pass through it—which they do without delay—into the jejunum. No photograph of the "cured" duodenum can be taken, in marked contrast to the state of things before the operation, when a most striking photograph of the distended duodenum is readily obtained.

Another proof of the efficacy of the radical treatment is shown in the stomach, which loses its constant pyloric spasm, so that the rate of emptying of the stomach becomes normal, or nearly so within a few months after the operation. This was exemplified to me in a most striking way recently when I reexamined a woman six months after she had been "short-circuited" by Sir Arbuthnot Lane. Before the operation she had furnished one of my most striking instances of the distended, "writhing" duodenum, and scarcely any bismuth had left the stomach after 6½ hours. Now (6 months later) the whole of the bismuth was in the rectum after six hours, a little having run up the descending colon, and the whole had been evacuated within 24 hours. The duodenum could not be photographed, the bismuth passing through it, little by little, without difficulty, so that the duodenum was never seen filled with bismuth, in striking contrast with its behavior before the operation. Thus the patient has been relieved of all the signs and symptoms of stasis, and her stomach and duodenum have been put out of danger; the duodenum is no longer infected with microbes from the stagnant ileum, and the duodenal distension and overloading of the stomach have been rectified.

I have given details of other aspects of stasis in a contribution to the *International Journal of Surgery*, for April, 1914, with a series of skiagrams illustrating many of the changes due to the disease.

Much progress is being made on both sides of the Atlantic in our understanding of Chronic Intestinal Stasis, but there is still scope for searching inquiry by surgeons, clinicians, radiologists, pathologists, and in fact all medical workers, in the realm which has been discovered by the far-reaching observations of Sir Arbuthnot Lane.

Here, in the New York Polyclinic, I see earnest investigators at work on the stasis problem. Dr. Quimby is attacking it from the radiological side; Dr. Hayes and others from the medical and pathological standpoint, while Dr. William Seaman Bainbridge is getting brilliantly successful results from the application of surgical measures to the relief of chronic intestinal stasis.

FOUR CLINICAL LECTURES.

HELD AT THE NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL DURING THE WEEK OF THE MEETING OF THE INTERNATIONAL SURGICAL CONGRESS.

Fractures and Burns.

Dr. John A. Wyeth, as President of the Faculty and Senior Surgeon of the New York Polyclinic Medical School and Hospital, after welcoming the visiting physicians and surgeons, spoke briefly on "Fractures and Burns," presenting illustrative cases of each. Dr. Weyth said in part:

I shall speak this morning of factures of a single bone, the patella. As you know, fractures of the patella are caused, as a rule, by violent contractions of the quadriceps extensor muscle while the leg is in extreme flexion. The bone may be broken by a direct blow or by a fall on the knee. A blow and muscular action may combine to break it.

The line of fracture is usually transverse, or nearly so, just below the middle of the bone. The break may occur, however, above or below this plane. Occasionally the bone is split longitudinally by direct violence, or it may be comminuted. Fracture of the patella is rarely incomplete, the sepa-

ration of the fragments varying from the smallest fraction of an inch to as much as two or more inches, and being wider at the inner than the outer border. This lesion occurs, in the majority of instances, between the ages of twenty and forty, and is more common in males than in females.

Because of the superficial location of the lesion the diagnosis is easily made, the depression between the separated fragments serving as a guide. Should the separation be very slight, lateral motion of one fragment upon the other will elicit crepitus.

In the treatment of this condition I have lately used a very simple, satisfactory, and painless method of holding the fragments in continuous apposition. After the transverse incision, which exposes both broken surfaces, the clot is washed out with hot sterile salt solution, and the frazzled periosteal edges are sutured together with fine linen, thus approximating the fragments. The skin incision is then sutured with chromicized catgut.

On a two and a half inch, half-curved Hagedorn needle, a very strong linen thread, twelve inches long (No. 4) is carried from side to side, deep into the substance of the ligamentum patellæ, just at its insertion into the lower rim of this bone. A like thread is inserted well into the substance of the quadriceps extensor tendon at the upper margin of the upper fragment. A light gauze dressing is placed over the line of incision, and over this the apposing ends of the two linen loops on each side, above and below, are tied tight enough to hold the fragments in close and continuous apposition, and without the possibility of overriding.

A dry gauze dressing covers the field of operation, and a plaster-of-Paris cast is applied, holding the knee immobilized for eight weeks. At the expiration of this time the holding sutures are removed and the fragments are held securely in apposition, while the knee is bent to not more than 20 degrees. The cast is reapplied and worn for four weeks longer.

The limb is now put to use, with the necessary precaution to prevent severe strain in overflexion for at least six months.

I have employed this method in the cases presented, with satisfactory results.

I wish also to present a case of an extensive burn of the face, neck, chest, and right arm. This patient was brought to the hospital in the ambulance last night, in a state of shock, after having been rescued from a burning building.

In connection with this case it may not be amiss to recall to your minds a few points concerning burns and scalds, which, as you know, may vary in degree from the mildest form which produces a simple inflammation of the epidermis, to the most severe form, which destroys all the tissues or organs or a part, and which may result in the death of the individual. The gravity of the prognosis is usually proportionate to the extent of the surface of the integument destroyed, rather than to the depth of the destructive process.

Burns of the head and face, such as the patient presented, are the most dangerous; those of the extremities the least grave. Recovery rarely follows destruction of one-third of the cutaneous surface. Death may result from shock, from ulcer of the duodenum, or from exhaustion following prolonged suppuration and septic absorption.

When a severe burn or scald is encountered the immediate indication is relief of pain by the hypodermatic administration of morphia, or by some form of opium given by rectum or stomach. The most convenient local remedy is a saturated solution of baking soda in water, with submersion of the burned surface, if possible, or a mixture of bicarbonate of soda and cornstarch, one teaspoonful of each to a quart of water. The dressing should be kept wet with the solution, which is applied freely to the burned area. After five or six hours the free application of the following mixture, made into an emulsion, will be found beneficial:

Ichthyol ..... ℥ss
Cotton-seed or olive oil ..... O.ss
Limewater ..... O.ss

This should be continuously applied for the first three to five days during the stage of acute inflammation.

In order to bring about rapid repair of the skin the following ingredients, mixed thoroughly, may be used:

Ichthyol ..... ℥j
Diachylon ointment,
White vaseline ..... āā ℥iij

If these remedies are not convenient, the following may be substituted with equal benefit:

Lead plaster,
Liquid albolene,
Lanolin,
Vaseline ..... āā ℥j

These are melted together, and, when cooling, 40 minims of ichthyol added.

Either of these ointments should be applied thickly on the soft, linty side of canton flannel, on surgeon's lint, or on several layers of sterile gauze. The application should be repeated daily at first, after opening all blebs. In opening the blebs care should be taken not to remove the epidermis of the bleb, as this may become revitalized, thus greatly accelerating the healing process. In changing the dressing it is important not to disturb new granulations, but simply to wipe over them. When healing is well under way the dressing need be changed only every second or third day.

In the treatment of the depression or shock which often follows severe burns, stimulation with whiskey or brandy, by enema or by mouth, is indicated, as well as the hypodermic injection of morphine. Physiological salt solution, introduced by the colon, or injected into the areolar tissue, is of great value when the burn is extensive and the shock profound. It should always be remembered that opium and alcohol should be given sufficiently cautiously to avoid too profound narcosis with the former, and with the latter increase in the fever reaction which follows when the patient rallies from the shock.

In an emergency, when the remedies mentioned may not be obtained, a coating of ordinary white lead, as mixed for use in painting dwellings, is an efficient protection when poured over the burn. Flour sprinkled over until all the excoriated surface is well hidden is a method of treatment which is applicable in almost any emergency. Rubber tissue, or oil-silk, sterilized and laid over the raw surface, with cotton batting applied over it, but never directly on the burned surface, is equally efficient. Lint, or a soft cloth, dipped in a 2 per cent. carbolized oil, may be employed directly on the burn.

No pressure should be exercised in holding the dressings in place. When the back and posterior aspects of the extremities are chiefly involved, the prone position is of necessity maintained.

Operations for Inguinal Hernia Under Local Anesthesia.

Dr. John A. Bodine presented a case of ordinary right-sided inguinal hernia, upon which he operated under local anesthesia, employing a solution of novocain, 1-500. Dr. Bodine said in part:

In operating under local anesthesia the nervous apprehension of the patient may be quieted to a great degree by a calmative demeanor upon the part of the surgeon and his assistants. This is also influenced by the patient's position upon the table. A position of comfort and relaxation should be maintained. If the arms are crossed above the head the patient will be "fidgety" throughout the operation.

In the effort to avoid bleeding points it is of great importance that the lower end of the incision should not extend beyond the lateral end of the suprapubic skin fold. It may be started as high as one desires. This incision may be deepened to the operative field without encountering a vessel large enough to demand a ligature, whereas, if the incision be extended an inch lower, a large number of ligatures will be required. Not only does the catgut thus employed, when softened by the tissues, invite sepsis, but, in cocaine work, it means a number of acute stabbing pains whenever a blood vessel is cut or tied. The incision so placed gives ample room by downward traction of the mobile skin, and nearly always permits the completion of the operation without the use of a ligature.

The line of incision is infiltrated with the novocain or other anesthetic solution throughout its extent. This is accomplished by introducing the needle just under the superficial epithelium. The anesthesia thus induced will permit the incision to be painlessly deepened to the aponeurosis of the external oblique. Upon splitting and reflecting the aponeurosis, the iliohypogastric nerve is anesthetized by injecting a little of the solution into the sheath of the nerve as high up as possible.

The ilio-inguinal nerve is also sought, but if it is not found the hernial coverings should be infiltrated in a straight line over the neck of the sac, and the incision deepened until this structure is reached. If omentum is excised it is generally gently withdrawn, ligated and amputated without additonal injection, and, in my experience, without pain. If, however, only the iliohypogastric nerve has been found some infiltration will be needed into the conjoined tendon. The cord is lifted from its position and the operation concluded according to the Bassini method.

Two suggestions are offered which have proved of worth to me: First, if a strip of gauze is used to hold up the cord it may, during the necessary manipulation, roll the cord on its long axis, and exposure to air may cause agglutination in this position of torsion. A wetted strand of catgut as a retractor will obviate this danger. Second, the deep suture should include but one-half the thickness of the conjoined tendon, thus avoiding strangulation.

Fractures.

Dr. Alexander Lyle presented three patients whose histories were briefly detailed, in part, as follows:

Case I.—This patient, a man forty-nine years of age, while working in the well of an elevator was crushed by the descending car, sustaining injuries to the pelvis. Upon being released from his confined position he complained of scarcely any pain, and it was not until he made an attempt to stand that the pain became noticeable.

Careful examination revealed a fracture of the pelvis, the exact extent of which could not be determined by palpation. Examination by rectum elicited no evidence of injury to this organ, and catheterization of the bladder showed no blood in the urine. Shock was not marked. The patient was placed in bed and a very tight wide muslin binder put about the pelvis. The following day an *x*-ray examination was made, which revealed a very marked bilateral fracture of the pelvis. In the skiagraph an irregular line of the fracture could be seen, starting from the crest of the ilium and extending down, terminating in the greater sciatic notch. There were no wounds in the skin.

The patient was observed very closely after being put to bed, in order to determine the presence of any internal injuries, but the abdominal viscera proved to be uninjured.

The treatment of this case, like that of all fractures of the pelvis, has been very simple. Straps of adhesive plaster were brought around the pelvis, in order to immobilize it, and this was reinforced by a firm muslin bandage. The patient's convalescence has been uneventful. He will be kept quiet in bed for eight weeks before he is allowed to stand.

Fig. 1.—Fracture of the neck of the humerus.

In all cases of this kind it is well to bear in mind the great danger of rupture of the urethra, of the bladder, and of the pelvic vessels. As soon as internal injury can be determined operation should be resorted to.

Case II.—The next patient, a woman of thirty-five years of age, sustained a transverse fracture of the surgical neck of the humerus, as shown in Fig. 1. The head of the humerus may be seen in the glenoid fossa, while the broken end of the shaft has pierced the pectoral muscles and lies immediately beneath the clavicle.

After several attempts to reduce this fracture and to hold it in position by mechanical means had failed, it was determined to open through the deltoid and replace the fragments. With complete ether anesthesia, the bone was exposed. Upon bringing the fragments together it was found that they could be dove-tailed into each other so firmly that plating or wiring was unneces-

sary. The tissues were then sutured, a small pad of cotton placed in the axilla, and a firm plaster-of-Paris spica applied.

The patient's condition being excellent, the dressing was not removed for four weeks. It was then taken down and a light one applied, which remained for two

Fig. 2.—Fracture of the neck of the humerus after reduction.

weeks longer. Following removal of this, massage and passive motion were used, the patient now having almost complete use of her arm. Fig. 2 shows the condition after operation.

Case III.—The third patient is a young man twenty-four years of age, who sustained a fracture of the lower third of the right femur, as shown in Fig. 3. He is a truck driver by occupation, and is consequently very muscular. It will be noticed in the plate that the muscles have contracted to such an extent that the fragments have overlapped fully an inch.

Formerly our treatment in such cases consisted in the application of Buck's extension, with sufficient weights attached to counteract the muscular force. Much of this traction was exerted upon or below the knee, and consequently knee-joint complications often became more severe than the fracture. We now have a very decided improvement in the line of traction in the Steinmann nail. This consists of a long spike of steel which is put through the lower end of the femur, just above the condyles, and by the use of tongs traction is exerted upon this, the knee-joint being left perfectly free.

Fig. 4 shows the femur after the Steinmann apparatus has been in service and twelve pounds of weight applied over the pulley. It will be observed that not only has the muscular force been overcome, but that the fragments have been pulled over an inch apart. At this point the weights were reduced to six pounds, and a plaster-of-Paris roll bandage applied over the lower two-thirds of the femur, in order thoroughly to immobilize the fragments that are now in perfect alignment.

The patient's convalesence was normal in every respect and he was able to walk out of the hospital, without the assistance of even a cane, at the end of eight weeks.

Cancer.

Dr. William Seaman Bainbridge presented a number of cancer patients. In some instances the patients had been operated upon at a previous time, in others operations were performed on this occasion. One particular case, belonging to the first category, suggested certain practical points with reference to the diagnosis and treatment of malignant disease, a partial report of which is here given:

The patient, a woman, seventy-one years of age, presented herself at the hospital in March, 1914, complaining of "throat trouble." In January, according to the history, another physician opened the left tonsil for "quinsy," the tonsil at that time being enlarged and painful. The diagnosis of syphilis had been made by one physician consulted, but the Wassermann reaction was negative, as was likewise the history. Before I saw her for the first time, in March, a small piece of the tonsil had been removed for pathological examination, and the pathologist had reported "inflammatory tissue."

When the patient came under my observation the tonsil was very much enlarged, indurated, and the surface ulcerated. The surrounding tissue was edematous and reddened. The patient complained of great pain, and of difficulty in swallowing. Three sections were removed from the ulcerated portion, and these were given to three independent pathologists for examination. One sent in the report, "inflammatory tissue"; the other two reported "sarcoma." The latter coincided with the clinical diagnosis, and, inasmuch as the mass was growing very rapidly, with danger of death from hemorrhage, immediate operation was advised.

On April 3, at the Polyclinic Hospital, the patient was operated upon under general ether anesthesia. The external carotid artery, including the ascending pharyngeal branch, was ligated, and the mass removed, with as thorough dissection as circumstances allowed.

The patient recovered from the operation, and experienced great relief from the dysphagia and general suffering caused by this enormous mass, which had filled almost the entire mouth. To have left this mass, involving the soft palate, and interfering with respiration and deglutition, would have meant early death, either from hemorrhage or from pressure upon the trachea and consequent interference with breathing. By tying off the large vessels it was possible to remove the tumor, to relieve suffering and to prolong life.

After the operation pieces of the tonsil were again sent to different pathologists for a verification, if possible, of the clinical diagnosis of malignancy. Of the four pathologists who examined these independently, three reported round-celled sarcoma, and one, inflammatory tissue.

A B

Fig. 3.—Fracture of the femur; A, front view; B, side view.

A case of this kind is fraught with a number of valuable lessons.

In the first place, it emphasizes the vital importance of making a careful and thorough diagnosis, even in apparently simple affections such as

"sore throat" and "quinsy." Many times, in the daily routine of the busy practitioner or of the hospital or dispensary physician, it is difficult to accord to each case the careful diagnostic consideration which it should receive. For this reason the conscientious and capable physician or surgeon may make errors in diagnosis which a little more time, care, and thought would obviate.

The same thing, it seems, applies to the pathologist. If, armed with an adequate history of the case and with the clinician's presumptive diagnosis of malignancy, the pathologist is content to examine one or two slides with negative results, and to render a negative report, he is very apt to fall into many pitfalls in diagnosis. Ordinarily, a few slides will reveal the true diagnosis, but it must not be forgotten that this may not be the case. Sometimes malignancy is established only after the examination of a large number of sections. Numbers of instances of this kind have been reported by myself and others. For this reason a negative pathological

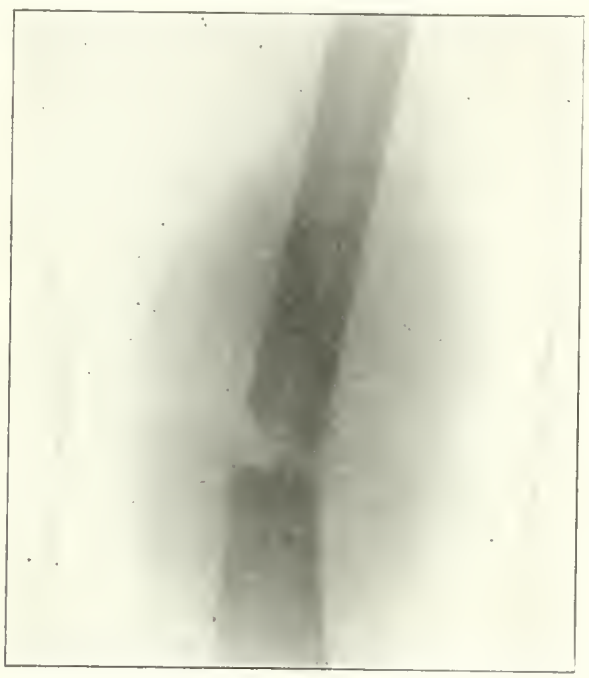

Fig. 4.—Fracture of the femur, shown in Fig. 3, after treatment with the Steinmann apparatus.

diagnosis should not be accepted in the light of positive clinical evidence of malignancy. The case under discussion illustrates this point.

In this connection it may be reiterated that adequate clinical data in each case should be given to the pathologist. It is fair neither to the pathologist, to the patient, nor to the surgeon himself, that the laboratory worker be expected, from the sections alone, to give reliable findings in all cases.

In the second place, the case emphasizes the importance of bearing in mind the question of the auto-infectivity of cancer. It cannot be positively stated, but, from the subsequent history, it is quite probable that the first operation, that of incising the tonsil for what was supposed to be "quinsy," or acute suppurative tonsillitis, stimulated malignant growth and accounted for the rapid development of the sarcoma. It is likewise quite fair to assume that this operation very materially affected the ultimate outcome of the case, for, while the patient, at the present time, is fairly comfortable, can breathe and swallow with ease, and is free from the danger of immediate death from hemorrhage, suspicious induration in the neck suggests early and rapid recurrence.

This patient's history recalls another case which came under my observation in this institution in 1908. Each illustrates, in a telling manner, the dangers of breaking down nature's barriers either for the purpose of taking specimens for microscopic study or through an error in diagnosis. In the case which I have just presented to you the growth was first cut into through a mistake in diagnosis, and afterward for the purpose of taking a specimen. In the other case to which I refer the second error was committed. In this instance a little boy, three years of age, developed a small tumor in front of the ear after a fall which caused a bruise in this region. The interne in the dispensary of the hospital to which the mother carried the child cut into this small lump and took out a section for pathological examination, telling the mother to return with the child in two weeks. The result was that the tumor increased enormously in size and with great rapidity, with involvement of the lymphatics of the neck and with metastases in the liver, spleen, and testes. Within about nine months from the time the child received the fall the condition had become inoperable, and the neoplasms, which proved to be sarcoma, irremovable. This was the condition when I first saw the patient, consequently no operation was performed. The child died early in December, the fall having occurred in February.

Such cases, one in a woman of seventy-one and the other in a child of three, emphasize the importance of keeping nature's barriers intact, in all instances where there is a doubtful question of malignancy. Instead of incising the unbroken skin or mucous membrane, the entire tumor should be removed and the section taken afterward for purposes of verification of diagnosis, and for determining the advisability of more extensive removal of tissue. If, perchance, nature's barriers have already been broken down, as in the case of the woman, a section may generally be removed without increasing the danger of extension. Under all circumstances, when the clinical diagnosis of maligancy is doubtful and a section is removed for microscopic verification or reinforcement, a prompt report should be insisted upon, in order that immediate operation may be resorted to if necessary. Inasmuch as negative pathological reports are not to be accepted in the face of positive clinical diagnosis, it is often advantageous to resort to frozen sections at the time of operation for the purpose of determining, in the light of the pathological findings, the extent of operative interference.

In closing I wish to reiterate once more the imperative duty of every surgeon who operates upon cancer patients to utilize all the diagnostic aids now at our command before pronouncing a condition malignant or non-malignant. Sins of commission may be just as disastrous to the patient as sins of omission in the matter of operative interference, and it is only by refinements of diagnosis, plus a goodly exercise of common sense, that we may avoid both pitfalls.

Diffuse Bilateral Sarcomatosis of the Kidneys.—U. Parodi reports a case of this condition in which there was in addition a diffuse infiltration of the liver and of the bone marrow with lymphocytes. Although the spleen was of normal size it was also the seat of a lymphocytomatosis.—*Archivio per le Scienze Mediche.*

SALVARSAN IN THE TREATMENT OF SYPHILIS;

WITH SPECIAL REFERENCE TO THE USE OF SALVARSANIZED SERUM IN CASES OF SYPHILIS OF THE CENTRAL NERVOUS SYSTEM.

By A. J. CROWELL, M.D.,
PROFESSOR OF GENITOURINARY DISEASES,
AND
J. P. MUNROE, M.D.,
PRESIDENT AND PROFESSOR OF NEUROLOGY AND CLINICAL MEDICINE IN THE N. C. MEDICAL COLLEGE,
CHARLOTTE, N. C.

ON our return trip from the International Congress of Medicine which met in London last August, one of us (Crowell) prepared a paper giving briefly the results of the latest work done in Prof. Ehrlich's Laboratory. This information was obtained from him while conducting our party through his laboratory and from his paper on chemotherapy, which he read at the above-named congress. Believing the members of this Society would be interested in some phases of this paper and especially that portion with reference to the use of salvarsanized serum in the treatment of certain cases of syphilis affecting the central nervous system we decided to reproduce this paper briefly and report some cases in which we have treated the spinal fluid with salvarsanized serum with apparent excellent results.

In his investigations to ascertain the way in which salvarsan acted upon the *Spirochæta pallida*, Professor Ehrlich found it somewhat different from what was first supposed. (In this, parenthetically, we will say that we believe he has laid the foundation upon which a chemotherapy may be built that will eventually result in the discovery of specific therapeutic remedies that will apply to all infections equally as efficient as "606" in the treatment of syphilis.)

It is now known that parasites are killed only by those drugs for which they have an affinity. These drugs are termed parasitatropic.

At first the theory was that "606" destroyed the spirochete by direct action, but further investigation shows it to be indirect as well, in that it fixes the remedy and excites the organism to the formation of specific antisubstances. This view is based upon the fact that a solution of salvarsan may be added to a tube which contains the microorganisms without either destroying them directly or diminishing their motility. If, however, these are injected into test mice they will not infect the animal, while those not so treated will. This shows that the salvarsan is absorbed by the spirochetes and so damages them as to prevent their increase in the human body. In this way the direct effect of the remedy by fixation is proved, but it acts in a different manner from what was first supposed.

Ehrlich found that when a race of trypanosomes had been rendered immune against all the allies of fuchsin it was still not immune against arsenic and other compounds. This shows that the immunity is of specific nature since it is limited to a definite class of substances and shows it to be a purely chemical process.

He also discovered that in the parasites there are different specific chemoreceptors which condition the fixation of salvarsan and other drugs at the same time. This gives an intelligent reason for the use of mercury with salvarsan in the treatment of syphilis and the only one I have ever heard. A complete knowledge of all chemoreceptors of a given parasite is the basis upon which rests the success of chemotherapy and which is gradually and surely being worked out. The larger the number of different chemoreceptors, therefore, which can be demonstrated, the greater is the possibility of a successful chemotherapy.

To apply specific remedies, it is necessary to select one chemically allied to one of the chemoreceptors of the parasite; one which is not only haptophoric (fixes) but is toxophoric (destroys) as well. "The toxophoric groups of synthetic drugs poison the protoplasm of the bacterial cell when a chemical affinity exists between the toxophoric grouping and the cell constitutent."

It is not a difficult matter to destroy germs in a solution, but the question of internal disinfection is a very difficult one, as the living parasites are within the infected organism. Such poisons as would destroy the germs in solution may be powerful cell poisons—organotropic as well as parasitotropic. Bichloride of mercury would be useless for this purpose, though a parasitotropic, yet so powerfully organotropic as to render it useless for such a purpose. Only such substances can be considered therapeutic agents of which a fraction of the dosis tolerata is sufficient to bring about therapeutic effects.

The organotropic effect of a drug is due to the fact that there are quite different chemoreceptors in the various cells of the body, just as found in the parasites. Ehrlich domonstrated that parasites possess a whole series of chemoreceptors different from each other. If we can discover a grouping in the parasites which has no analogue in the organs of the body, the possibility of constructing an ideal remedy is accomplished. Such a remedy would be innocuous, as it is not fixed by the body cell and strikes the parasites with full intensity.

The theoretical and experimental work is easy, but the step from the laboratory to the bedside is difficult and dangerous, on account of the idiosyncrasies of men to certain drugs. This supersensitiveness does not exist in animals. Salvarsan is so constructed that a manifestation of a supersensitiveness to it is one of the rarest occurrences, owing to the fact that the protoplasmic cell receptors do not fix the drug, but it is fixed only by the cell receptors of the spirochete.

The apparent idiosyncrasies following its administration in man are due to errors in its preparation and administration. Too large an addition of alkali injures the veins used for injection, too small an amount causes blood coagulation and leads to thrombosis. Lengthy shaking of the solution and standing in the air oxidize the drug and make it much more toxic, forming an oxide of arsenic.

Secondly, certain constitutional diseases, such as Addison's disease and status lymphaticus, cause a supersensitiveness to arsenic compounds. Here the resisting power is lowered in addition to the supersensitiveness to the drug.

The seat and location of the disease may bring about a supersensitiveness excited by a local reaction. The rapid disintegration of a focus of parasites liberates toxins, which irritate the tissues and produce a hyperemia and swelling. This is of no significance if the reaction center is in the skin, but if it is located in the neighborhood of vital organs (brain) then this reaction may bring about changes inimical to life, or may even cause death.

We believe this fact calls for a thorough investi-

gation of each patient coming under our care. Also the administration of iodide of potassium previous to giving salvarsan for the liberation of such central focuses is very advisable in many cases. These facts make the treatment of syphilitics not only a difficult but a responsible task.

To free the body of spirochetes by means of one or two injections of "606," it is necessary that the dose be in proportion to the advance of the disease, since a definite number of parasites is destroyed by a definite dose of the remedy. The amount of the drug must be increased in proportion to the multiplicity of the parasites. These important facts call for the earliest treatment of syphilis possible, since not only is it far more possible to stamp out the disease with one or two doses of salvarsan in the early stages, but there is danger of irreparable injury to health or even the possibility of producing death in the late stages by endotoxins. Here the dark field illuminator and serological aids in our diagnostic work are of greatest importance.

The causes which make it possible to rid the system of parasites are not only the drug administered but the action of the antibody produced by the cell under the influence of the drug. This is especially true of the protozoa.

Spirochetes may escape the destructive action of both the drug and antibody and be changed into a new serum-proof variety known as a relapsing group. This is especially true of the trypanosomes, in particular those of syphilis. Such parasites offer very great difficulty in their treatment, since the auxiliary forces of the body fail to act. This makes it quite important to destroy the parasites all at once by means of drugs. Their great power of adaptation makes it possible for a single germ to cause a fresh outbreak of the disease.

The great difficulty then of a complete sterilization of the body by means of a single dose of medicine is due to the fact that there are in the body what are known as dead spaces or corners, one of which is the hollow situated between the spinal cord and the dura. This is filled with fluid almost entirely free from cells and albumin, the cerebrospinal fluid. The cells by which this fluid is secreted are highly impervious to most of the constituents of the organism such as albumin, and permit only a limited quantity of substances with small molecules to pass through. The drug with more complex molecules are, like albumin, kept back and unable to exert their influence on the cerebrospinal fluid; this makes it well nigh impossible to destroy parasites located here.

Another reason for deficient sterilization is that among the large number of parasites there may be some unaffected by salvarsan. This fact does not play an important part in the course of fresh infection, but is quite important in connection with certain cases of syphilis characterized by innumerable relapsing crops of the microorganism.

Here one of two things may occur: First, it is possible for a drug-proof stock to be formed by adaptation, or, in other words, a strain may arise which is immune to the action of the drug. Second, the continual formation of relapsing crops can bring about a change in the chemoreceptors of the parasites and result either in an increased or a reduced power of resistance to the drug. We should expect, however, that the relapsing crops would become much less sensitive to the action of the drug than the original stock. These few facts show how difficult it is to cure syphilis in the late stages. In fact, I heard no less an authority than Professor Wassermann say at the International Congress in London that he doubted very much our ability to cure syphilis (up to the present) where it had existed for three years. Others thought it possible but only after a long series of injections—the so-called serial treatment.

I believe it possible to cure almost any case at any stage of the disease by treating the dead spaces in the body and persisting in the treatment sufficiently long.

Efforts have been made to render the epithelium more previous to therapeutic agents—so to change the cells as to allow more of the therapeutic agent to pass into the cerebrospinal fluid. This has proved unsuccessful.

Direct injection of the remedy into the cerebrospinal fluid has been tried, but Professor Ehrlich is of the opinion—as the result of experimental work on animals—that these membranes are too sensitive for this, and advises the use of salvarsanized serum according to the plan suggested by Swift and Ellis of the Rockefeller Institute. The technique of this operation is as follows: First, give the salvarsan and draw into sterile tubes one hour thereafter about 50 c.c. of blood. Serum is obtained from this and 30 c.c. of a 40 to 50 per cent. solution of this serum is injected into the spinal fluid twenty-four hours thereafter. The saline solution for diluting this serum should be made of freshly distilled water. It is always well to withdraw as much as 30 c.c. of the cerebrospinal fluid before injecting the serum, and more if the pressure is high. This is practically always the case when the cell count is high and the globulin and Wassermann reactions are positive. It is well to bring the pressure down to 30 mm. before injecting the serum. This plan of administering the remedy obviates the ill effects of the drug on the sensitive central nervous system and at the same time makes it possible to apply the curative agent in sufficient quantities.

Our investigations have not gone sufficiently far for us to say what are the positive indications for this method of treatment. At present, it appears to us the cases most likely to be benefited by this plan of treatment are those that have a spinal fluid with high pressure, a high cell count, a positive globulin and a positive Wassermann reaction.

The following cases which we have treated upon this plan with results obtained are reported by Dr. Munroe:

As the clinical forms of syphilis of the nervous system are largely abstractions yet for the definite application of therapeutic measures it is well to have distinctive lines drawn to indicate the recognized clinical types.

It is not the purpose of this paper to discuss this classification, but it is necessary to refer briefly to the fact that a distinction is hereby made between cerebral syphilis and paresis. There are those who maintain that there are no real distinctions to be drawn. The majority perhaps say that the distinctions are justified not only by clinical symptoms but by the histological pathology, the different biological tests and the diverse results of therapy. It is only true to state that these differences are gradually melting away under the influence of more accurate clinical examinations and fuller laboratory researches.

Strictly speaking, one should say paresis is one form of cerebral syphilis, the spirochetes which are

being now recognized as the etiological factor having been demonstrated in the brain tissue. Yet, therapeutically, the same results have not been obtained as the condition known as cerebral syphilis; and for this reason it may be well, for the present at least, to observe the distinction.

There have been those who have contended that the therapeutic tests draw a decisive line, arguing that the paretic cases would not yield at all to treatment. It is true that paresis and tabes have been most resistant to ordinary treatment and it has been in hope of overcoming this resistance that we have been experimenting with a view to reaching more directly the diseased tissues. In the application of this treatment, however, we have not confined our work to paresis but are trying this method as described above on all cases that show disease of the central nervous system. We are not prepared yet to give the final results of this treatment because sufficient time has not elapsed.

Our present purpose is to make a preliminary report of a few cases in which the results, up to the present at least, appear nopeful.

The important points to be considered in connection with the diagnosis are: (1) Wassermann of the blood; (2) Wassermann of the spinal fluid; (3) pressure of the spinal fluid; (4) cell count of the spinal fluid; (5) globulin reaction of the spinal fluid; (6) condition of pupillary reflexes.

Favorable therapeutic results are predicated on improvement in any or all of these features, together with improvement in the general symptoms of organic nervous diseases.

Case I.—Mr. W. Cerebral Syphilis.—Had been treated previously with five doses of salvarsan, intravenously. At the beginning of the present course of treatment the blood Wassermann was very positive, the spinal fluid Wassermann weakly positive, globulin weakly positive, cell count 11, pupils negative. Five treatments of salvarsan were given intravenously and in three of the treatments salvarsanized serum was injected into the spinal cavity. After this course of treatment the blood became negative. Spinal fluid negative. Cell count reduced to 3. The general symptoms had entirely disappeared.

Case II.—Mr. L. Paresis.—In this case blood Wassermann strongly positive, spinal fluid Wassermann positive, globulin reaction positive, cell count 48. The pressure in this case was 160 mm., Hg. Pupils small and sluggish. Three treatments were given of salvarsan and in connection with two of them salvarsanized serum was injected into the spinal cavity. Mercury inunction was also used. As a result of these treatments the blood became negative to Wassermann, cell count 5, and globulin negative. Pressure not taken. I regret to say that this case did not remain with us long enough to complete even one course of treatment and has not been under observation since these treatments and I am quite sure that he will need further treatment and examination if any permanent results are to be expected.

(Since this report was made the patient has returned and has been given more treatments of salvarsanized serum. Mental condition still good and Wassermann negative. Cell count 5.)

Case III.—Mr. H. Cerebral Syphilis.—Blood Wassermann positive. Special Wassermann positive. Globulin weakly positive. Cell count 22. Pressure was not taken. Pupils negative. Five salvarsan treatments were given and along with three of the five, salvarsanized serum was injected into the spinal cavity. After treatment, cell count was 3, globulin slightly positive, and Wassermann on spinal fluid and blood negative. General symptoms very much improved.

These are three of a number of cases now under treatment and observation and a mere outline is given showing improved conditions of spinal fluid in every case. We have not gone into details of the general symptoms, but as intimated these have shown marked improvement, some of them disappearing all together. It is our purpose at a later time to report these and other cases with tabulated statements of results. It is too early yet to predict what the ultimate results will be nor do we yet claim that this should be recognized as a firmly established mode of treatment.

COMPARATIVE WASSERMANN, COBRA, AND GLOBULIN TESTS IN SYPHILIS.

WITH A REPORT OF ONE HUNDRED AND FIVE REACTIONS.*

By WILLARD J. STONE, M.D.,

TOLEDO, OHIO.

In 1909 Weil[1] described the resistance of luetic red cells to cobra-venom hemolysis as a reaction of possible value in the diagnosis of syphilis. He found that while normal red cells were more or less rapidly hemolyzed with cobra-venom dilutions varying from 1 in 20,000 to 1 in 40,000, luetic red cells showed resistance to hemolysis with these dilutions. The reaction consisted in adding a portion of a 4 per cent. suspension of washed red cells to an equal portion of venom dilutions of the following strengths: 1 in 10,000, 1 in 20,000, 1 in 30,000, and 1 in 40,000.

The resistance of luetic red cells to cobra-venom hemolysis has been considered to be due to (1) a decreased lecithin cell content as a reactive phenomenon to the luetic toxin; (2) that the cells had become lecithin-fast, with the result that less lecithin was available in a free state for hemolysis; (3) that the cholesterin of luetic red cells was increased which inhibited hemolysis in certain dilutions; or (4) that neither the lecithin nor cholesterin content was altered, but that a dissociation had occurred with inhibition of hemolysis by the latter substance.

According to Pascucci[2] the stromata of red blood cells consist of one-third lecithin and cholesterin and two-thirds protein substances; while Wells[3] states that dried red blood cells contain, according to Hoppe-Seyler, lecithin 0.3 to 0.7 per cent. and cholesterin 0.2 to 0.3 per cent. In the process of hemolysis cobra venom unites with lecithin to form what has been designated by Keyes[4] as cobra-lecithin, or by von Dungern and Coca[5] as desoleolecithin.

It has been stated by Abderhalden[6] that if red cells were washed absolutely free from serum, hemolysis did not occur with cobra venom. He does not mention the species of cells or dilutions of venom employed. He found that if a very small amount of serum or lecithin was added hemolysis took place. Lecithin was apparently necessary for hemolysis. Human red cells contain, at least under normal conditions, sufficient lecithin for the union with cobra venom. With human normal red cells hemolysis occurs after washing three to five times with sodium chloride solution in the centrifuge to remove the serum, and without the addition of lecithin. It is possible, however, that enough serum remains, even though inappreciable, to influence hemolysis.

Whatever may ultimately prove to be the correct biochemical explanation, it is apparently true that luetic red cells behave differently than normal cells with the dilutions of cobra venom concerned in Weil's test. It should be mentioned in this connection that the resistance of red cells to hemolysis is

*Read before the American Association of Immunologists, Atlantic City, June 21, 1914.

not, in the strict sense, specific for syphilis, any more than the Wassermann reaction is specific for syphilis experimentally or clinically. Instances are common in which positive Wassermann reactions have been obtained by competent observers in a variety of conditions, such as scleroderma, scarlatina, leprosy, polycythemia, erythema multiforme, and non-luetic granulomata, such as pseudoleucemia. In addition, jaundice and chronic alcoholism interfere with complement fixation by the Wassermann method. According to Stafford the inoculation of tubercle vaccine may produce, in tuberculous patients, a positive Wassermann reaction. Nor is the reaction positive in more than 55 per cent. of latent tertiary syphilis. An analysis of 4,200 cases from the published reports of Corson-White[7], Schwartz,[8] Wassermann[9], Fleischmann,[10] Swift[11] and Cummer and Dexter[12] shows average positive Wassermann reactions in latent syphilis in 52 per cent. On the other hand, Schwartz obtained positive cobra reactions in one patient with scleroderma, in another with Raynaud's disease, and in three patients with advanced carcinoma, all of whom gave negative Wassermann reactions.

The Wassermann reaction is, however, a very important, if not the most important, confirmatory adjunct to a clinical diagnosis, and when repeatedly positive means syphilis in by far the larger percentage of cases. A negative reaction has less value in suspected latent tertiary conditions. While the cobra reaction does not fulfill all desired requirements in the diagnosis of syphilis, it nevertheless has an important field in clinical diagnosis when repeatedly positive, and is of value as an index for continued treatment of the disease.

In an article on this subject by Schottstaedt and myself[13] the technique of the reaction was described, together with the results obtained, to March 27, 1912, in an examination of 43 normals and controls and 87 patients with syphilis. Since then the test has been used in the examination of 105 individuals, making a total of 235 to May 1, 1914. Except in one instance mentioned below, the reaction has never been found positive in any individual in whom it was felt that syphilis could probably be excluded from a survey of the family and personal history and the physical examination. In the first test made, which was upon the blood of a patient with morbilliform erythema, the reaction was positive. It has never been possible to check this reaction with a Wassermann test, as the patient did not return. On the other hand, the cobra reaction has been negative in a number of instances of well defined luetic affections and in some others, in which from the clinical examination a luetic basis was suspected. The discrepancies were not great, barring the instances of early secondaries five and six weeks after infection. In these instances the clinical diagnosis was not in doubt.

Field[14] has reported the results obtained in a comparative study of the Wassermann and cobra-venom reactions in syphilis as follows:

	Primary (Per Cent)	Secondary (Per Cent)	Tertiary (Per Cent)	Questionable and Negative Cases (Per Cent)
Wassermann positive.	70	87	75	30
Cobra venom positive ..	76	75	73	40

Technique of the Cobra Test.—The cobra test has been used by me during the past year as follows: 2 c.c. of blood are drawn from one of the veins at the bend of the elbow into a 5 c.c. glass syringe containing 2 c.c. of 2 per cent. sodium citrate solution to prevent clotting. The blood-sodium citrate suspension is then placed in a 15 c.c. graduated centrifuge tube in the ice-box for a few hours, since less autohemolysis subsequently occurs, in the process of washing the cells, if the cells remain in contact with the serum and sodium citrate solution. The citrate and serum are then removed with a pipette and the tube filled with 0.9 per cent. sodium chloride solution, which is then placed in the centrifuge and the cells washed for about ten minutes at a speed of about 1000 revolutions per minute. This washing process is repeated three times, the supernatant solution being removed with a pipette and fresh sodium chloride solution added. After the last washing the cells are found to be packed in the bottom of the tube. It has been found convenient to remove with the pipette any cells in excess of 0.5 c.c. and then add enough 0.9 per cent. sodium chloride solution to bring the suspension to 12.5 c.c., which makes a 4 per cent. suspension of cells. The thumb is then placed over the end of the tube, which is inverted three or four times to secure an even suspension. One cubic centimeter of the 4 per cent. suspension is now added to each of four small test tubes. This is done with an accurate pipette. One cubic centimeter of cobra venom dilution, 1 in 15,000, is added to the first tube; 1 c.c. of dilution, 1 in 20,000, to the second tube; 1 c.c. of dilution, 1 in 30,000, to the third tube, and 1 c.c. of dilution, 1 in 40,000, to the fourth tube.

The tubes are then covered with tin-foil and placed in the incubator for one hour at 37° C. At the end of one hour the tubes are gently shaken and placed in the ice-box for about 24 hours. At the end of this period if the blood is negative all tubes will show complete hemolysis. If hemolysis has occurred in the first tube, to which the 1 in 15,000 dilution of venom was added, but has not occurred in the others, the tubes are gently shaken, to bring into suspension any cells at the bottom, and are placed in the ice-box for one hour longer. At the end of this period, if hemolysis has not occurred in the tubes to which the 20,000th, 30,000th and 40,000th dilutions of venom have been added, the reaction is positive. Hemolysis practically always occurs in the tube to which the 1 in 15,000 dilution of venom has been added. This tube consequently serves as a check upon the reagent. In normal bloods hemolysis occurs in a 4 per cent. suspension of cells to which an equal volume of cobra-venom dilutions as high as 1 in 40,000 to 1 in 60,000 has been added.

In a 4 per cent. cell suspension from patients with an active tuberculosis, hemolysis occurs six or seven times more rapidly with the dilutions concerned in this test than occurs with normal cells, a fact noticed by Schottstaedt, which was mentioned in our earlier article.[13] Noguchi[15] had, however, mentioned that in tuberculosis the red corpuscles are subnormal in point of resistance to hemolytic agents. The test as here applied serves to differentiate latent tuberculosis from syphilis in many cases, since in the former the red cells seem to be hypersusceptible, while in the latter the cells are hyposusceptible to cobra-venom hemolysis.

In luetic bloods, about two months after the primary lesion, hemolysis is retarded or does not

occur in a large majority of the cases, in the tubes to which dilutions of venom 1 in 20,000 or above have been added. The only apparent exceptions occur when the patient has had enough treatment to be considered clinically cured, or unless such a patient falls into the latent tertiary class, 25 per cent. of which may not give a positive reaction by this test, while the Wassermann fails also in approximately 50 per cent.

Remarks Upon the Technique.—Too rapid centrifugation in the electric centrifuge while washing the cells will render them so fragile that hemolysis of luetic cells may occur and the reaction be considered negative. A centrifugal speed of about 1000 revolutions per minute does not entail this risk. Failure to recognize this possibility has probably militated against the results in the hands of some workers.

It is important to make the 4 per cent. suspension of cells accurately, since an excess may be sufficient to inhibit hemolysis in some of the tubes and produce the effect of a positive reaction in normal blood.

It is also important to have the venom dilutions accurately and freshly made. With this end in view it has been found best to powder the crystalline venom to permit more accurate weighing. This is done by rubbing it in a mortar with a few drops of commercial benzine, which is allowed to evaporate, leaving an amorphous powder. The venom powder is then weighed into 0.5 mg. portions, and each portion placed in a small dry corked test tube until ready for use. If 1 c.c. of 0.9 per cent. sodium chloride solution is added to a tube containing 0.5 mg. venom, a stock 1 in 2000, dilution is secured from which the subdilutions are readily made as follows:

A—1 c.c. stock solution plus 4 c.c. 0.9 per cent. sod. chlor. sol. = 5 c.c. of dilution 1 in 10,000.

B—2 c.c. sol. —A— plus 1 c.c. 0.9 per cent. sod. chlor. sol. = 3 c.c. of dilution 1 in 15,000.

C—1 c.c. sol. —A— plus 1 c.c. 0.9 per cent. sod. chor. sol. = 2 c.c. of dilution 1 in 20,000.

D—1 c.c. sol. —B— plus 1 c.c. 0.9 per cent. sod. chlor. sol. = 2 c.c. of dilution 1 in 30,000.

E—1 c.c. sol. —C— plus 1 c.c. 0.9 per cent. sod. chlor. sol. = 2 c.c. of dilution 1 in 40,000.

It will thus be seen that 0.5 mg. venom made into the 1 in 2000 stock dilution is sufficient for two tests. The subdilutions hold their potency for at least four or five days if kept in the ice-box.*

Fresh specimens of venom should be tested and the hemolytic activity determined on normal and luetic red cells.

In performing the Noguchi butyric acid test for increased globulin the following procedure has been followed: To 1 c.c. of a 10 per cent. solution of pure butyric acid in physiological salt solution, in a test tube, 0.2 c.c. of blood serum or cerebrospinal fluid is added. The mixture is heated to boiling, 0.2 c.c. of normal sodium hydrate solution is added, and the mixture again boiled. In the presence of increased globulin a definite flocculent precipitate occurs either immediately or within an hour or two. In performing the test on cerebrospinal fluid only clear fluid, free from blood, should be used. The same procedure is applicable to clear blood serum, from which all blood cells have been removed by centrifugation. Hemoglobulin stained serum should be discarded. Part of the Wassermann tests were performed with the anti-sheep method; in the balance the anti-human method was followed.

Summary.—The conclusions here given comprise comparative cobra, Wassermann, and globulin tests in one hundred and five individuals. All "suspicious" reactions have been excluded.

1—In 30 normals and controls the Wassermann and cobra tests were negative. In 6 of these the globulin test was negative in spinal fluid. In 90 other normals and controls the cobra test was negative.

2—In 22 patients with secondary syphilis the Wassermann and cobra tests were positive. In 5 of these the globulin test was also positive in the spinal fluid, while in 7 the globulin test was positive in the blood serum.

3—In 7 patients with active and latent tertiary syphilis the cobra blood test was positive, and the globulin tests in blood serum and spinal fluid were positive.

4—In 24 late tertiary and clinically cured cases both Wassermann and cobra tests were negative.

5—In 1 patient with cerebral lues the Wassermann and cobra tests were negative, while the globulin test was positive in blood serum and spinal fluid.

6—In 7 patients with syphilis the cobra test was positive and the Wassermann was negative, while in 14 instances the Wassermann was positive and the cobra negative. Two of the latter were instances of early secondaries five and six weeks after infection, in which the diagnosis was not in doubt.

I am indebted to Dr. Richard Schottstaedt for his assistance in the tests and the tabulation of results.

*Those who may desire to secure cobra venom should address inquiries to the Loomis Laboratory, 414 E. 26th St., New York, where it may be possible to secure a limited amount by importation. One gram is sufficient for 4,000 tests.

Old Injury to Elbow.—C. Woodward reports the case of a child aged 7 years who fell on a stone and was treated with a splint for "fracture of a small bone and a bone out of place." All movements were remarkably free but the arm was very weak. The skiagram showed an anterior dislocation of the radius and the site of fracture of the ulna.—*Proceedings of the Royal Society of Medicine.*

BACKACHE AND POSTERIOR PARAMETRITIS.

By ADOLPH JACOBY, M.D.,

NEW YORK,

CLINICAL ASSISTANT GYNECOLOGIST, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

BACKACHE is one of the commonest complaints met with in ambulatory gynecological patients. Of 120 unselected cases, 64 complained chiefly of backache, either alone or associated with other symptoms. These 53 per cent. of women were anywhere from 20 to 50 years of age, married and hence subject to the various incidents and accidents of married life. It is, therefore, of great interest to the physician to go into this subject a little more fully, and determine as far as possible the causative factors which make this one symptom so prominent, and of such importance to the majority of women.

Of these 64 patients, 54 complained of backache only, and 10 complained of backache associated with a bearing down sensation. Of the 54 complaining only of backache, 38 were found upon examination to have a posterior parametritis; 10 had posterior parametritis associated with a retroversion, one had posterior parametritis with a descensus uteri, and 5 had retroversion. Of the 10 cases of backache associated with a bearing down sensation, 4 had a posterior parametritis associated with descensus uteri and retroversion, 2 had posterior parametritis associated with descensus uteri, 2 had retroversion associated with descensus uteri, and 2 had retroversion only.

From the above, it will be readily seen that posterior parametritis stands out preeminently as a cause of backache, being present in 55 of the 64 cases, or 86 per cent. We will, therefore, take up the subject of posterior parametritis.

Parametritis is that form of pelvic inflammation involving the cellular connective tissue of the pelvis, or in other terms, a pelvic cellulitis. Pelvic cellulitis involving the uterosacral ligaments, and usually its peritoneal folds, called Douglas' folds, has been designated by Schultze, posterior parametritis.

The cellular connective tissue is especially plentiful around the cervix at the junction with the vagina and at the base of the broad ligaments. Its function here is to act as a support and buffer to the pelvic organs. It is plentifully supplied with lymphatics, especially behind the cervix and at the base of the broad ligaments. This makes it readily susceptible to inflammations, which, when started, spread readily in the meshes of the connective tissue.

Parametritis, in general, is either acute, subacute, or chronic. We are here chiefly interested in the subacute and chronic forms, and shall consider only the acute form very briefly.

The acute form usually follows infection through a laceration of the cervix during childbirth, or trauma caused by surgical operation, making a point of entrance for bacteria. Two or three days after one of the above causes has become operative, there is usually a chill followed by fever and a rapid pulse. As a rule, pain is not a prominent feature, although there may be a sense of discomfort and heat in the pelvis. On examination the vagina is found to be hot and pulsating. An exudate, which spreads in the cellular connective tissue of the pelvis, may be felt filling out the fornices. This exudate is at first soft and elastic, but later as the edema is absorbed becomes harder and more sclerotic. If pus formation takes place, there is an increase in the chills and fever and sweating, and a point of softening or actual pointing can usually be made out on examination.

In the subacute form the inflammatory process comes on more slowly so that in about two or three weeks after a labor or abortion the patient, instead of improving becomes progressively weaker, complaining of a feeling of malaise, feverishness, and pain in the back. An examination at this time will reveal evidences of cervical catarrh, possibly ectropion, and the presence of an infiltration behind the cervix. The subacute form most commonly involves the sacro uterine ligaments. The patient may go on in this fashion for some time without any improvement, and slowly pass into a chronic condition. The edema of the infiltrated tissue gradually becomes absorbed, leaving on examination, hardened, thickened, and sclerosed uterosacral ligaments, which are stretched tightly from the back of the cervix to the sacrum on either side of the rectum. This condition can be more readily made out by a combined examination, putting the middle finger into the rectum and the index finger into the vagina behind the cervix, in this way getting the posterior parametrium between the two fingers. An attempt to lift the uterus by putting two fingers behind the cervix and making pressure upward toward the symphysis, causes severe pain in the back, due to the stretching of the tense, indurated uterosacral ligaments. This is a similar pain to that complained of by the patient, but of greater intensity. This condition may go on for months and years, the only symptoms being backache and leucorrheal discharge due to the cervical catarrh.

The diagnosis of this condition is not difficult. The loss of elasticity of the posterior fornix, lack of mobility of the cervix, palpation of the thickened uterosacral ligaments through the vagina and through the rectum, and pain on stretching the ligaments similar in character to that complained of by the patient, makes the diagnosis of posterior parametritis comparatively easy. Perimetritic adhesions must be differentiated from; the two conditions often being present together. In perimetritis, bands of adhesions pass from the fundus or the whole posterior surface of the uterus, whereas, in parametritis, the only bands to be felt are the two thickened uterosacral ligaments. If more than these two bands are felt, it is evidence that both conditions are present.

We now come to the question of treatment which is, after all, the most important as far as the patient is concerned, for the patient does not come to us primarily for a diagnosis, although without it correct treatment cannot be instituted, but for the relief of her complaints. The method of treatment pursued by us is highly successful in meeting her requirements. Here, again, we refer more especially to the subacute and chronic forms.

In the acute form rest in bed is essential. The diet is limited to fluids, the bowels are kept freely moving, preferably by saline cathartics. An ice bag or ice coil is placed on the abdomen, and tepid or cool vaginal douches of 1 per cent. lysol or 1 to 5000 bichloride of mercury are given twice or three times a day. If the exudate goes on to pus formation, an incision must be made either into the posterior fornix, the broad ligament or wherever the abscess points, and the cavity must be drained.

When the fever has disappeared, and the process has become subacute, more active treatment can be

pursued. The object of the treatment at this stage is to cause absorption of the exudate. This is accomplished by painting the cervix and fornices with tincture of iodine, followed by pouring into the vagina one-half to an ounce of glycerin or boroglycerin, and packing the vagina lightly with gauze. Hot compresses can be applied to the abdomen. Hot douches of bichloride or lysol are made twice a day by the patient.

In the chronic form, where the uterosacral ligaments are indurated and thickened, the object of the treatment is to cause the absorption of the exudate and a return of the tissues to their normal elasticity. To do this we aim to produce an increased blood supply and hyperemia to the affected area, which will the more readily carry off the inflammatory products. At the same time we must treat the causative cervicouterine catarrh. This is accomplished in the following manner: At every vaginal examination of the patient, gentle but firm massage of the posterior fornix is made, in order to stretch the uterosacral ligaments. This is more effective if it is made soon after a hot douche has been taken. The vagina is then cleansed, and any cervical mucus is removed by gentle swabbing with cotton or by suction. No intracervical or intrauterine manipulation or treatment is used, as this does not help the condition, but merely tends to drive the inflammation further along the genital tract. Any erosions present are treated. This treatment depends upon the nature of the erosion. For simple erosions we have an excellent remedy in pyroligneous acid. This is applied pure by squirting about ½ ounce directly upon the eroded area, and then drying up the excess with a cotton sponge. A change is noticed at once in the appearance of the erosion; from an angry red it immediately becomes pale, the pyroligneous acid having a mild antiseptic and a powerful astringent action. For the follicular and papillary erosions, more powerful causties are necessary. Pure carbolic acid is applied with an applicator directly to the erosion once or twice a week. In obstinate cases 50 per cent. zinc chloride may be used. Then we paint the external os, the cervix, and the vault of the vagina with tincture of iodine. This has a twofold action, being a powerful antiseptic, destroying any bacteria it may reach, and a good counterirritant. The blood supply to the diseased tissues is thereby increased, and a hyperemia is produced which aids in absorbing the products of the inflammation.

About an ounce of pure glycerin or boroglycerin is poured into the vagina and the vagina is packed with gauze (an ordinary 4-inch gauze bandage answers very well for this purpose). The gauze is packed first into the posterior fornix, then into the anterior and lateral fornices, and into the vagina. One end of the gauze is left protruding so that the patient may withdraw it. This is usually done at the end of twenty-four hours.

This produces a marked serous outpouring, glycerin being one of the most powerful dehydrating agents at our command, and thereby washing away the infected material lodged in the depths of the uterine and cervical glands, and also softening the exudate, thus aiding in its absorption. This method of pouring glycerin into the vagina and packing with gauze is far superior to the use of cotton tampons saturated with medicaments. In the first place the glycerin bathes the entire vault of the vagina and the cervix. Secondly, it secures better drainage, the gauze allowing the fluid drawn out of the tissues readier escape than cotton. Thirdly, it gives better support. Every one who has used the cotton tampon knows that it usually rolls into a little ball in the vagina, and becomes tucked away, offering very little if any support. Whereas, by packing the fornices and the vagina with gauze, the uterus is held up and the dragging downward is prevented, thus materially increasing the patient's comfort by stopping or relieving the backache. We do not use ichthyol, as we do not believe it has any action, and in addition it has a very disagreeable odor and musses everything up, much to the patient's annoyance.

After the gauze is removed, a hot vaginal douche is given. The douches are made twice or three times daily, as hot as can be comfortably borne, about 110° F., using 4 quarts of water, at an elevation of about 1 to 2 feet above the pelvis. The douches are taken lying down with the hips elevated, the solution being allowed to run in an out slowly, so that the entire douche takes from 20 to 30 minutes. The drug used has not very much influence as it is the prolonged heat which is the beneficial agent, causing a prolonged hyperemia and increased absorption. The drugs commonly used are boric acid, 1 dram to the quart, for a mild cleansing douche; bichloride of mercury, 1 to 10,000; potassium permanganate, 1 to 5,000, or lysol 1 per cent. for an antiseptic douche, and equal parts of zinc sulphate and tannic acid, 1 dram to the quart, for an astringent douche when hypersecretion is present. The glycerin and packing treatment is repeated three times a week. In addition hot sitzbaths help in the production of hyperemia and increased absorption. The Nauheim baths or salt baths are very beneficial by their action in improving the general circulation. These may be taken once or twice a week.

This is the course of treatment we have been pursuing for many years with uniformly excellent results. Great patience is required on the part both of the patient and of the physician, as the treatment takes several weeks and months before improvement is noticed. But in the end it is well worth it, as it obviates the necessity for operative procedure in a great number of cases, and in those where operation is unavoidable, a previous course of this conservative treatment will have done much to soften up the parts and increase absorption, so that the operation may be performed with greater ease and with much better results, to the great gratification of the patient.

ABRAMS' METHOD OF TREATMENT IN ANEURYSMS.

By ALBERT ABRAMS, A.M., M.D., LL.D.,

SAN FRANCISCO.

The writer believing that this method of treatment is deserving of more consideration than has been accorded to it wishes to present additional data bearing on the subject.

When his first article was submitted to the editors of several medical journals it was rejected for the reason that it was tantamount to a violation of tradition to attempt treament of an incurable (sic) affection by the simple method proposed. The Medical Record, ignoring the attitude of the formalist and traditionalist, published the writer's primary contribution' on the subject.

Since this time, the writer has reported in the *British Medical Journal*[2] and *La Presse Médicale*[3] forty cases in his own practice of thoracic and abdominal aneurysm symptomatically cured within a few weeks by the concussion treatment with absolutely no other adjuvant measure, not even rest.

The cases were all advanced and many of them have been seen after a period varying from two to five years without any recurrence of symptoms. Other physicians have reported in the journals and through correspondence equally good results.

The writer has cited the details of his treatment elsewhere, notably in his work on "Spondylotherapy" (5th edition), MEDICAL RECORD[4] and in "International Clinics."[5]

To eliminate the personal equation the writer wishes to direct attention to a few additional observations made by other physicians. In a masterly and exhaustive monograph[6] by the Minerbis of Italy, the value of the aortic reflexes has been corroborated. The elicitation of the aortic reflex of contraction is the essential object achieved by the concussion method of treatment.

Dr. C. B. Kohlhausen of New Mexico, in his report of an advanced case of aneurysm of the thoracic aorta treated by Abrams' method says as follows: "After the first treatment, lasting ten minutes, I was utterly amazed at the change in the condition of the patient and after six days all his symptoms had disappeared and he was symptomatically well."

Dr. M. L. H. Arnold Snow[6] presents a series of pictures showing variations in volume of an aneurysm superinduced by elicitation of the aortic reflex of contraction.

This writer comments as follows: "These changes induced by vibration have been previously only studied clinically, so far as I know. They are here put on record, with remarks on the interpretation of the skiagrams." Skiagraphic records of the aortic reflexes have been previously made by Dr. George Jarvis and the writer.[7]

Dr. Snow's report may be briefly summarized: The patient's skiagram showed an immense aneurysm and the skiagrams taken before and after treatment demonstrated conclusively that an aortic aneurysm could be contracted by elicitation of the aortic reflex of contraction. Dr. Snow concludes that the marked relief afforded the patient by the method of Abrams was additional clinical evidence of a reduction in the dimensions of the aneurysm.

Dr. Isaac Robinson, Toledo, Ohio, presents his own anamnesis as follows: "Age 62. No specific history. While surgeon of the Pennsylvania Railroad in 1897 my voice became husky and so continued. In addition to the dysphonia, pains developed in the chest and there was paroxysmal dyspnea. Numerous diagnoses were made by many physicians, but it was not until 15 years after the inception of my trouble that a correct diagnosis of thoracic aneurysm was made by aid of the Roentgen rays. At this time my symptoms were accentuated and it was impossible to lie on either side for a minute at a time. The pains became so intense that recourse was had to narcotic medication. After the first treatment by Abrams' method morphine was discontinued. After several weeks' treatment practically all the symptoms have subsided and the voice is nearly normal. When treatment was commenced the aneurysm projected at least three inches beyond the thoracic surface. At the present time of writing it projects about one-half inch."

Dr. Robert Houlie, Paris, France, presented to the Société de Médecine[8] a patient with aneurysm of the thoracic aorta who was treated by Abrams' method. Absolutely no results were achieved by different methods of treatment until the concussion method was instituted. The results were surprisingly rapid. "After three treatments the patient was practically transformed; the violent pains have evanesced, the pulsations have diminished, the patient can lie in any position without inconvenience and his dyspnea has lost its intensity. The physical signs also show great amelioration."

Dr. B. E. Witte, San Antonio, Texas, reports the following cases of aneurysm of the abdominal aorta which simulated gastric lesions: "Female, 42 years, suffered for three months from persistent emesis, hematemesis and violent abdominal pains. A diagnosis of ulcus ventriculi was made and a laparotomy was performed. The operation revealed a large aneurysm of the abdominal aorta. After recovery from the operation I executed treatment according to the method of Abrams. After three *séances* vomiting and hematemesis ceased, and at the present time of writing the patient is symptomatically cured. Another patient, a barber, was likewise laparotomized for a supposititious gastric ulcer. Here the operation likewise demonstrated an aneurysm of the abdominal aorta. Concussion treatment at the seventh cervical spine resulted in a subsidence of the symptoms and the patient was enabled to resume his occupation."

Dr. George O. Jarvis, Ashland, Ore., reports the following cases: Aneurysm of the subclavian artery. The diagnosis in this case was substantiated by six physicians. Abrams' treatment for aneurysm conducted daily for a period of one month was followed by the evanescence of all subjective signs, the heart and aorta within the normal boundaries and the disappearance of the swelling, pulsations, and bruit over the affected artery. *X*-ray plates demonstrated no signs of an aneurysm. Aneurysm of the thoracic aorta and abdominal aorta. The aortic arch was dilated and measured 20 cm. in its transverse diameter. The abdominal aorta likewise showed decided dilatation with aneurysmal thrill and murmur. Morphine was necessary to relieve the severe pains of the patient. Four weeks after Abrams' treatment was commenced the patient, who was bed-ridden, was able to walk two or three miles daily. Eventually morphine was discontinued absolutely and there was a disappearance of all subjective symptoms. Dr. W. W. Britt, Tonawanda, N. Y., recently reported a patient with aortic aneurysm who was practically rescued "from his deathbed" by this method of treatment.

THE ANTITOXIC RÔLE OF THE LIVER.

IN 1910 Billard and Dechambre discovered that the fluid obtained by the autolysis of the liver of the pig destroys the toxicity of a mortal dose of cobra venom. Subsequently Billard found that the hepatic autolysate has the same action upon other poisons, such as the tetanus toxin, the venom of the viper, cocaine, curare, and strychnine. In 1912 Barlocco demonstrated that the hepatic autolysate of the pig counteracts the toxicity of the diphtheria poison to an extent depending upon the length of time during which the toxin and autolysate are in contact with each other. A further study along this line has been conducted by Amilcare Bertolini, who reports his results in the *Annali dell' Istituto Maragliano*, June 22, 1914. His experiments were carried out with the liver of the ox and the findings of Barlocco were corroborated. But he went further. He sought to determine the exact mechanism of the detoxicating process. It was found that a solution of lactic acid of a strength equal to that present in a measured volume of liver subjected to autolysis for 48 hours, has the same effect upon the diphtheria toxin as the hepatic autolysate itself. If the acidity of the latter is neutralized the detoxicating action on the diphtheria toxin is removed.

The question now arises whether the detoxicating function of the liver is brought about by a purely chemical reaction or whether it is effected through the medium of a catalytic agent. It has been well established that the process of catalysis is inhibited by the presence of an acid even in the greatest dilution, and is accelerated by the presence of the hydroxyl ions. This would seem to signify that if catalysis has really a detoxicating action this would be favored by a slightly alkaline medium while it would be inhibited in the presence of the hydrogen ions. In other words, alkalinity would favor the antitoxic function, while acidity would not impair the virulence of the toxin. The conclusion is drawn that the mechanism of the detoxicating action of the liver is of the nature of an ordinary chemical reaction and does not call into play a catalytic agent.

The above facts are applied by Bertolini in a theory as to the relation of the liver to the various toxins that may be introduced into or formed in the human body. The diphtheria toxin, like all other poisons, accelerates autolysis, as the result of which there are set free a larger quantity than normally of substances having an acid reaction, thus favoring a more intense detoxicating action upon the diphtheria poison. It would thus appear that the autolysis excited by the toxins becomes a means of defending the organism against these toxins.

A NOTABLE SURGICAL CLINIC

IN the issues of the MEDICAL RECORD for September 19 and 26 a large amount of space available for original communications has been given to papers read and reports of clinics held at the New York Polyclinic during the week of the International Surgical Congress which met in this city last spring. In honor of this Congress the Faculty of the Polyclinic requested the surgical staff of the institution to open its doors to the visiting members of the profession, and to arrange a series of lectures and clinics. Accordingly, on four days of that week the surgical lectures and demonstrations were given which have here been reproduced for the benefit of our readers.

This was the first occasion on which the International Surgical Congress had met in this country—in fact the first time that it had been held elsewhere than in Brussels, the city of its birth. One can but wonder where the next Congress will meet and when—when indeed the enmities and hatreds engendered by this European strife will have become so far dulled that any really international meeting will be possible, even of medical men. These are wont to boast in their gatherings, in the intervals of war, that science is truly international, untinged by jealousies of race and nation, but when war comes they find that after all blood is thicker than water and love of country is more compelling than love of science.

We are getting a little away from the papers of which we purposed to speak, but there is one more thought suggested by the fact of the war and that these papers were read at a post-graduate institution. In no country has post-graduate instruction been carried further than in our own. It was in this city that post-graduate teaching was first organized on a practical basis, independent of universities and undergraduate medical schools, and American medicine owes much to Roosa and Wyeth who founded the Post-Graduate and Polyclinic schools. They were pioneers in a new field and their respective institutions and others modeled after them in most of the larger cities of the Union have done much for the uplift of medical standards in this country. These schools for post-graduate instruction in America will now have the opportunity to demonstrate their worth. "See America first" will be no longer the slogan only of the patriotic American physician, for all must heed it, as there will be nowhere else anything to see medically for some time to come. While the War of the Nations lasts and probably for some time thereafter the young medical men in this country will perforce come to the conclusion that it is not essential to their individual success to trek to the European clinics immediately after graduation and thereafter as often as may be when the vacation

season comes round. They will find there is as much to learn in America as in Germany or France and that it is not necessary to go abroad to pick up ideas originating here and merely relabeled on the other side. In other words the misfortunes of Europe may tend to develop greater initiative, certainly greater self-reliance, in the American medical profession than it has hitherto manifested.

We have still said nothing of the papers published in this and the previous issue. But they speak for themselves, and the authors of them, foreign guests and members of the Polyclinic staff alike, are all too well known to need an introduction to our readers.

A NEW OPERATIVE PROCEDURE IN PULMONARY TUBERCULOSIS

In a recent issue (August 1, 1914) we called attention to the development and present world-wide acceptance of the value of the production of artificial pneumothorax, according to the methods of Forlanini and Murphy, in the treatment of pulmonary tuberculosis. It has been noted by all observers that in cases of approximately identical involvement of the lung the value of the treatment was almost directly proportionate to the completeness of the pneumothorax, and that the efficiency thus directly depended upon the absolute or comparative absence of adhesions between the visceral and parietal pleuræ. In the presence of extensive adhesions, collapse of the lung has sometimes been obtained by making use of the methods employed for the obliteration of the pleural cavity in cases of long-standing empyema, namely, extensive rib resection (Estlander's operation), sometimes with modifications approaching the type of the Schede or Delorme technique. These operations are accompanied by considerable shock and loss of blood and are not well borne by the enfeebled tuberculous patient; the mortality has been so high as to make the operation unjustifiable in view of the uncertainty of cure, or even improvement.

To allow patients with extensive pleural adhesions to receive the benefit of the pneumothorax treatment, Torek (*Surg., Gyn. and Obst.*, July, 1914) has devised the operation which he calls "Interpleural Pneumolysia," and which consists in making a large incision in the sixth or seventh intercostal space under intratracheal insufflation or some other form of differential pressure, finding the line of adhesion between the parietal and visceral pleura, and following this line of cleavage over the entire surface of the affected lung. When this has been completed the lung is left collapsed as far as the development of fibrous tissue in the lung itself will allow, the restored pleural cavity is left filled with air, and the pleural cavity and overlying soft parts are closed without drainage. Subsequently nitrogen injections are employed in accordance with the indications such as obtain in the ordinary uncomplicated case. Certain modifications in technique may occasionally be necessary, as in the presence of the rupture of a superficial abscess of the lung, and due attention is given to these possibilities by the author. It should also be stated that many essential points in the technique have necessarily been omitted in this brief résumé. One case is reported, and the result seems to justify the belief that Torek has made an important contribution to the surgery of pulmonary tuberculosis.

PARAMENINGOCOCCUS MENINGITIS.

In 1909 Dopter isolated from the nasopharynx the parameningococcus which was later found to be responsible for some cases of epidemic meningitis that were not influenced by the antimengitis serum. The parameningococcus is differentiated from the meningococcus chiefly by the fact that it is not agglutinated by the antimeningitis serum, that it possesses specific agglutinins and precipitins, and that it does not evoke the peritoneal and intravenous reactions described by Dopter. In the peritoneal reaction it is found that if meningococci are injected intraperitoneally into guinea-pigs twenty-four hours after antimeningitis serum has been similarly injected, in twenty to thirty minutes the peritoneal exudate is found to contain few or no free meningococci. In the intravenous reaction it has been shown that if a mixture of antimeningitis serum and meningococci is injected into a vein in a guinea-pig there result in a few minutes convulsions, dyspnea, coma, and death. The importance of differentiating between the meningococcus and the parameningococcus resides in the fact that there is now available an antiparameningococcus serum which is curative in cases caused by the latter organism.

A case of this nature was reported at a recent meeting of the Société Médicale des Hôpitaux of Paris by Brodin and Vallery-Radot (*Presse Médicale*, July 1, 1914). The fact that the patient did not respond to the use of antimeningitis serum led the authors to suspect that they were dealing with an infection caused by the parameningococcus. This was identified as such by Dopter. In spite of the fact that the patient was in coma, the use of the antiparameningococcus serum was followed by immediate improvement and speedy recovery. The lesson which is taught by this experience is that when a case of epidemic meningitis does not respond to the use of antimeningitis serum one should resort to the antiparameningococcus serum, even though the identity of the organism in the particular case may still be in doubt.

At the same meeting Dopter and Pauron reported a simple method of distinguishing between the two organisms. In many instances an ordinary agglutination test suffices for this differentiation. But in the case of both specific sera there may occur at times coagglutinations, that is to say, the presence of group agglutinins may cause the agglutination of both microorganisms by the same serum. To obviate this difficulty the authors employ in addition to the specific agglutinating sera, a so-called saturated antimeningitis serum which will agglutinate the meningococcus but will not agglutinate the parameningococcus. The ease with which this reaction may be performed enables one at the start to make the differential diagnosis and then choose the suitable specific serum and so lose no time in the treatment of a given case.

The Humane French Bullet.

Writing in the *Münchener medizinische Wochenschrift* of August 25, Prof. Walther Traube says the German soldiers have a great dread of the French bullets, believing them to be poisoned, and during the battles around Mülhausen many French cartridges were brought to him for examination to determine this point. Where the bullet fitted into the shell of the cartridge there was a black band which the Germans regarded with great suspicion, but Straub found it was nothing more than a harmless ring of lacquer. The bullet itself was made of copper, zinc, and nickel, and on analysis was proved to contain no arsenic, phosphorus, or antimony, therefore a bullet "of very good material." It had a copper jacket so very thin that it seemed to be galvanized on, and being a mere film it was incapable of damage if split off from the core; the bullet therefore could not be "dumdumed" by nicking or filing its nose. Straub concludes, as a result of this examination, that "as far as the expression may be allowable in such a case, the French infantry bullet must be regarded as humane." This opinion, we may add, is confirmed by the experience of the German army surgeons. They have found the wounds inflicted by the French rifle to be of little moment unless a vital organ is pierced. Even wounds of the lung, as we learn from the letter of a surgeon in one of the army hospitals in Munich, are regarded as trivial. These effects are very different from those of the spitz bullet employed by the Germans and the English.

Insufflation of the Bladder and Air Embolism.

It is a practice with some surgeons, preparatory to a suprapubic cystotomy for cystitis, calculus, or neoplasm, to distend the bladder with air in order to facilitate access to this organ. This practice is not without danger, for according to Antonio Poddighe (*Giornale Internazionale delle Scienze Mediche*, June 30, 1914) there have recently been reported in the literature two cases in which autopsy revealed the existence of air embolism from the bladder. Aged individuals are particularly susceptible to this accident. Various opinions have been advanced as to the route by which air enters the blood-stream from the bladder. Thus, one observer believes that air traverses the ureter and penetrates the renal vein; another advances the view that air passs through the ureter into the renal tubules and thus enters the blood; still another holds that the air goes directly into the veins of the bladder or of the prostate. Poddighe subjected this question to experimental investigation, using dogs for the purpose. He found that in the case of the healthy bladder the insufflation of air into the viscus with considerable force through a metal catheter is not apt to rupture the organ inasmuch as the air returns to the exterior between the catheter and the urethra. In these cases there is rarely even a laceration of the vesical mucosa. If the catheter is tied tightly in the urethra at the extremity of the penis, rupture of the entire vesical wall, but first of all of the mucosa, may be caused by forcible insufflation. In neither of the above modes of distention does the air ascend the ureters to the kidneys. If the air is forced directly into the ureters under considerable pressure for a long time, there is no evidence that it reaches the circulating blood through the renal parenchyma. The insufflation of air directly into a large vein in the bladder produces embolism even with slight pressure. There can be no doubt that the vesical veins, lacerated by overdistention of the viscus, represent the only path by which air embolism follows insufflation of the bladder. The practice therefore is not a risky one provided there is no evidence of a sclerotic condition of the vessels of the bladder or of a solution of continuity in its mucosa.

Pemphigus Vegetans Cured (?) by Salvarsan.

Pemphigus vegetans is known as a malignant bullous affection, the lesions of which ulcerate and then undergo vegetation, so that they come to simulate syphilitic condylomata. It occurs in successive outbreaks and otherwise resembles pemphigus foliaceus of which it is assumed by some to be a mere variation. At a meeting of the Naturhistorischmedizinischer Verein of Heidelberg last spring, Antoni reported a typical case of pemphigus vegetans (*Muenchener medizinische Wochenschrift*, July 21). It was treated with apparent benefit by intravenous injections of saline solution, but as it is a disease of some tendency to remissions no strict claim of control over the process could be made, because when the next exacerbation followed the serum was powerless. The patient then received at short intervals three injections of salvarsan. The sudden and overpowering effect of the latter could not have been a coincidence, the lesions coming under complete control. The patient has now been free from new bullæ for a month. The possibility of a protozoan cause was strengthened by a peculiar blood find at the beginning of the last exacerbation.

The Heart of the Child.

One of the happiest adaptations of Nature is found in the functional peculiarities of the infantile heart. From the embryological viewpoint alone, the evolution of this organ, from a simple pulsating tube to a complicated four-chambered pump, is one of the wonders of biology. An interesting philosophical inquiry into the special manner in which the heart of the child is adapted to the needs of the growing organism is presented by Armbruster in the *Zentralblatt für Kinderheilkunde*, August 1, 1914. He notes that the increased rate of the heart beat in early life diminishes the burden of the heart in the following manner: the amount of blood pumped at each impulse is correspondingly smaller; the aspirating force of the right heart is increased; and the rapidly developing heart muscle is more effectively nourished. The author attributes the relative immunity of very young children to infectious diseases to the rapidity with which the blood flows through the arteries, which rapidity makes it difficult for microorganisms to gain a foothold in the blood stream.

News of the Week.

Conference of Sanitary Officers.—The fourteenth annual conference of sanitary officers of the State of New York was held at Saratoga Springs October 15, 16, and 17, 1914, under the presidency of Dr. Hermann M. Biggs, Health Commissioner of the State.

The Death Rate in New York.—There were 1,206 deaths in this city during the week ending September 12. This gives a death rate of 11.27 per

1,000, as gainst 11.50 for the corresponding week of 1913. There was not a single death from scarlet fever, a very unusual happening, and deaths from diphtheria, croup, whooping cough, and pneumonia showed a marked decrease. The mortality of infants under 1 year of age decreased by forty-seven deaths, but for infants between 1 and 4 years there was an increased mortality of forty-one deaths. The death rate for the first thirty-seven weeks in 1914 was 13.73, against a rate of 14.25 for the corresponding period last year, a decrease of more than one-half a point.

The Danger of Surgical Practice in Mexico.—According to the Dallas *News*, Dr. N. T. Moore, formerly secretary of the El Paso County Medical Society, is being held as a prisoner at Culician, Sinaloa, Mexico, because he performed an operation upon a resident of that city which resulted in his death.

University of Illinois, College of Medicine.—The following faculty appointments have been made in this college for the session of 1914-15: D. A. K. Steele, senior dean and head of the department of surgery; Charles Spencer Williamson, professor of medicine and head of the department; Charles Sumner Bacon, professor of obstetrics and head of the department of obstetrics and gynecology; Julius Hays Hess, associate professor of pediatrics and head of the division of pediatrics; Norval Pierce, professor of otology; Joseph C. Beck, associate professor of laryngology and rhinology and head of the division; Oscar Eugene Nadeau, instructor in surgical pathology; A. O. Shoklee, associate professor of pharmacology; Roy L. Moodie, instructor in anatomy; C. S. Smith, instructor in physiological chemistry.

Physicians' Signatures Registered at the Department of Health.—In order to prevent the practice of unqualified healers the law provides that physicians desiring to practise medicine in the State of New York must have secured a license from the State Board of Regents and have recorded this license at the office of the county clerk in the county in which the physician intends to practise. In the city of New York, in addition to the above requirements, section 160 of the Sanitary Code makes it mandatory for physicians practising within the city limits to register at the office of the Bureau of Records of the Department of Health in the borough in which they intend to practise. To do this the physician must present his license or the county clerk's certificate. No certificate of death, birth, or still-birth will be accepted from a physician who is not registered with the Department of Health.

Twenty-nine Notifiable Diseases in New York City.—At a meeting of the New York Board of Health on August 25 section 133 of the Sanitary Code was amended to read as follows: "It shall be the duty of every physician and of the commissioners or managers or the principal, supervisor, superintendent, or physician of each and every hospital, public institution, or dispensary in this city to report to the Department of Health in writing the full name, age, and address of every person suffering from any one of the infectious diseases included in the list appended, with the name of the disease, within twenty-four hours of the time when the case is first seen: Anthrax, Asiatic cholera, diphtheria (croup), dysentery (epidemic), epidemic cerebrospinal meningitis, glanders, gonorrheal ophthalmia, hookworm disease, leprosy, malarial fever, measles, mumps, paratyphoid, plague, acute anterior poliomyelitis (infantile paralysis), pulmonary tuberculosis, rabies, rubella (German measles, rötheln), scarlet fever, septic sore throat, smallpox, tetanus, trachoma, tuberculous meningitis, typhoid fever, typhus, varicella (chickenpox), whooping cough, yellow fever."

A Public Clinic in Genitourinary Diseases will be held every Thursday evening at 8:30 by Dr. Abr. L. Wolbarst at the West Side German Dispensary and Hospital (New York School of Clinical Medicine), 328 West Forty-second street. The clinics will begin on October 8 and end in April. Physicians and medical students are invited.

Hospital News.—The Whitinsville (Mass.) Hospital was opened for inspection on September 12 and 14 and will soon be ready for the reception of patients.

The new King's Daughters Hospital in Norfolk, Va., was opened on September 14.

The Huber Memorial Hospital in Pana, Ill., was opened with appropriate ceremonies on August 31. The hospital was erected at a cost of $100,000, the fund for this purpose having been started with a gift of $25,000 from the late Mr. Huber.

A tuberculosis sanatorium will be erected near Windsor, Minn., on the shore of Fish Lake, by the Southwestern Minnesota Tuberculosis Association, whose membership comprises representatives from eight counties in that State.

Fire in the Elm City Hospital, New Haven, Conn., in the early morning of September 10 damaged the building slightly.

The Minnesota State Medical Association will meet in St. Paul on October 1, under the presidency of Dr. A. E. Spaulding of Luverne. The secretary is Dr. Thomas McDavitt of St. Paul.

The Utah State Medical Association will meet at Salt Lake City September 29 and 30 under the presidency of Dr. J. F. Critchlow.

Obituary Notes.—Dr. OSCAR R. LONG, for many years medical superintendent of the Michigan State Hospital for the Criminal Insane at Ionia, died suddenly on September 10 at the age of 64 years. He was a graduate of the Detroit Homeopathic Medical College in the class of 1873.

Dr. PATRICK HENRY MANGAN of Central Falls, R. I., a graduate of the Kentucky School of Medicine, Louisville, in 1903, died at his home, after a long illness, on August 12.

Dr. GWYNNE P. HARRISON of Sharpless, W. Va., a graduate of the University College of Medicine, Richmond, Va., in 1901, was run over and instantly killed by a railroad train on August 12.

Dr. LEVI D. SHEETS of Glen Ridge, N. J., a graduate of the New York University Medical College in 1849, and a veteran of the Civil War, having served as surgeon in the Second Army Corps, died at his home on August 25, aged 88 years.

Dr. THOMAS S. NAGLE of Allentown, Pa., died on August 28 of typhoid fever. He was born January 29, 1847, and was graduated from the Long Island Hospital Medical School in 1870.

Dr. MARGARET H. VAN TINE, 86 years old, one of the first women to practise medicine in the State of New York, died Thursday at the Home for the Aged in Brooklyn, where she had been since her retirement fifteen years ago. Her practice in Brooklyn extended over a period of forty years.

Dr. L. H. SPALDING of Peoria, Ill., died suddenly in Rochester, Minn., on August 23, while hurrying to the bedside of his son, recently operated upon at St. Mary's Hospital. He was born in 1845 and was

a graduate of the University of Maryland School of Medicine in 1869.

Dr. JAMES H. SANDERSON of Worcester, Mass., died of pneumonia on August 28, at the age of 47 years. He was a graduate of the College of Physicians and Surgeons, New York, in 1890, and served as interne in Bellevue Hospital.

Dr. MORRIS LONGSTRETH of Cambridge, Mass., died in Barcelona, Spain, the latter part of August, aged 68 years. He was born in Philadelphia and was a graduate of the Medical Department of the University of Pennsylvania in 1869 and of the Jefferson Medical College in 1872. He had been in poor health for some time.

Dr. CORNELIUS TOWNSEND FORD of Mullins, S. C., died in Wilmington, N. C., on August 26 at the age of 80 years. He was born at Page's Mills, S. C. He began the study of medicine in Philadelphia and later went to New Orleans, receiving his degree from the New Orleans School of Medicine in 1861. He served as surgeon in the Southern Army during the Civil War and at its close began the practice of medicine in Mullins.

Dr. JAMES B. GARVEY died at Dunmore, Pa., on August 23 at the age of 71 years. He was graduated from the College of Physicians and Surgeons of Baltimore in the class of 1884. He was a member of the Lackawanna Medical Society and of the Medical Society of the State of Pennsylvania and a Fellow of the American Medical Association.

Dr. GEORGE H. B. SWAYZE died at Philadelphia on August 22 at the age of 81 years. He was graduated from Jefferson Medical College in the class of 1859. He served as assistant surgeon in the One Hundred and Seventy-eighth Pennsylvania Infantry during the Civil War. He was founder of the Medico-Chirurgical College of Philadelphia and at one time dean of the faculty and professor of obstetrics and gynecology.

Dr. JOHN R. UMSTAD died at Norristown, Pa., of typhoid fever on August 26 at the age of 58 years. He was graduated from Jefferson Medical College in the class of 1876. He was a member of the Montgomery County Medical Society and of the Medical Society of the State of Pennsylvania and a Fellow of the American Medical Association.

Dr. EDWARD HOTTENSTEIN died at Kutztown, Pa., on August 27 at the age of 83 years. He was graduated from Jefferson Medical College in the class of 1853.

Dr. ALEXANDER HAZARD of Philadelphia, died at Atlantic City on August 25 at the age of 67 years. He enlisted as a medical cadet in the United States Army during the Civil War and he was graduated from the medical department of the University of Pennsylvania in the class of 1867.

Dr. S. P. PECK of Hinton, W. Va., died suddenly on September 2, at the age of 55 years. He was a graduate of the College of Physicians and Surgeons, Baltimore, in the class of 1877. He was for many years a surgeon of the Chesapeake and Ohio Railway.

Dr. WILLIAM FREEMAN NYE of Minneapolis died on August 31 at Lake Minnetonka. He was born in 1857 and was a graduate of the Northwestern University Medical School, Chicago, in 1878.

Dr. WILLIAM E. BARNARD of Union Grove, Ala., died on August 31, aged 33 years. He was a graduate of the University of Alabama School of Medicine, Mobile, in 1905.

Dr. J. H. BELL, for fifteen years surgeon of the White Star Steamship Line, died in Liverpool on September 15. He had been surgeon successively on the *Baltic*, *Cedric*, and *Celtic*, and was on the *Adriatic* at the time of his death.

Dr. DEVILLE J. MAYER of Junction City, Kans., died at his home in that city on September 9 after an illness of several months. He was born in 1862 and was a graduate in medicine of the University of Michigan in the class of 1893.

Dr. JOHN HARRY LANE died suddenly at his home in Medora, Ill., on September 9. He was born in 1844 and was a graduate of the Washington University Medical School, St. Louis, in 1876.

Dr. GEORGE IVERSON ROSS of Canton, Mass., died suddenly on September 13 at the age of 67 years. He was born in Newport, R. I., and was a graduate of the College of Physicians and Surgeons, Baltimore. He practised for a time in Canterbury, Conn., but for thirty years had lived at Canton.

Dr. CHANDLER C. LARKIN died in Mankato, Minn., on September 3 of valvular disease of the heart. He was born November 17, 1884, and was graduated from the medical school of the University of Minnesota in 1911.

Dr. GEORGE F. JENKINS of Keokuk, Iowa, died on September 4 at the age of 72 years. He was a graduate of the Missouri Medical College, St. Louis, in 1867. He had been president of the Iowa State Medical Society and vice-president of the American Medical Association.

Dr. LOUISE DODSON HOLMES of Athol, Mass., died on September 11 in Springfield of angina pectoris. She was born in Greensboro, N. C., in 1867 and was a graduate of the Woman's Medical College of Cincinnati in 1895. She had practised medicine in Athol for the past nine years.

Dr. TRUMAN G. WILKINSON of Williamsport, Pa., died at Reading, Pa., on September 3 at the age of 36 years. He was graduated from the Medico-Chirurgical College of Philadelphia in the class of 1899.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

WAR NOTES—WOUNDED, HOSPITALS, AND AMBULANCES—INDIAN OFFERS OF HOSPITAL PROVISION—DELHI MEDICAL ASSOCIATION—CHADWICK GOLD MEDALS FOR ARMY AND NAVY MEDICAL OFFICERS—THE APPROACHING SESSIONS, SCHOOLS, AND GENERAL MEDICAL COUNCIL—OBITUARY.

LONDON, September 11, 1914.

THE war absorbs the attention of the whole community. The work of the army medical service has naturally a special interest to the profession, intensified by the eager questioning of the doctor wherever he goes as to ambulances, the wounded, their transport, the Red Cross, and similar war subjects. The hospitals of the metropolis and the provinces placed a proportion of their beds at the disposal of the government and many wounded have experienced the comfort so provided, for arrivals began more than a week ago. One of the first batches, if not the first, upward of 300, were taken in at the London Hospital, about as many at the Royal Herbert, more than 100 at Plymouth, and so in other towns. The Dreadnought has 200 at the disposal of the Naval Medical Department. An "Allied Forces Base Hospital" has been fully equipped with 200 beds under the charge of Major E. Miles, surgeon of the Cancer Hospital, and is at
